ABSTRACT

Marine evaporites provide a unique insight to the variation in paleo-seawater chemistry throughout the Phanerozoic Era which in turn provides information about various geologic processes and earth history. This study examines changes in paleo-ocean chemistry and evaporite mineralogy by utilizing GeoDeepDive and Macrostrat to derive records of evaporite occurrences and abundance throughout the Phanerozoic. This study provides a more comprehensive list of epsomite and sylvite evaporites, and their temporal occurrence, than has been available to date (Appendix 1). Changes observed in the abundance of epsomite, sylvite, halite, calcium sulfate and dolomite help contextualize changes in paleo-seawater composition and global sea-level fluctuations. Normalizing marine calcium sulfate occurrences to calcium sulfate and halite occurrences (RAC) shows a distinct difference in the abundance of calcium sulfate-bearing evaporites before and after the Mid-Devonian. Prior to the Mid-Devonian the RAC was highly variable and after this it stabilized. Changes in the RAC were evaluated using batch evaporation modeling attempts in PHREEQC that suggest the main drivers of increased calcium sulfate relative to halite could be caused by increases in the product of Ca^{2+} and SO_4^{2-} which could constrain the assumption of a constant product of Ca^{2+} and SO_4^{2-} used in the calculation of seawater chemistry through fluid inclusion analyses. The occurrence and temporal abundance of marine evaporites yields unique insights into the role of global sea-level and its relationship to evaporites and their formation. Evaporite abundance tends to increase during periods where there is significant continental flooding following a decrease relative sea level, then relative sea-level subsequently decreases again. The RAC tends to be elevated when global sea-level is decreasing and lower when sea-level has stabilized or is increasing. Dolomite abundance compared to these global evaporite records suggest that dolomite is primarily formed during continental flooding and less likely during widespread evaporite formation.

List of Tables

Table 1.1: List of evaporite minerals and their chemical formulas by evaporite mineral group (from Table 2 in Babel and Schreiber, 2014).....7
Table 2.1: Table of terms queried and documents returned from GDD. Bibliography contained in Appendix 1.1.....30
Table 2.2: List of variables used in the text mining program to evaluate correct and incorrect instances of mineral – stratigraphic name tuples The same steps are taken for distant mentions that extended beyond an individual sentence of an evaporite mineral and a stratigraphic entity. This approach is used is to match minerals to units that may not have a full stratigraphic name in the text, but the root words are used in the instance. Applying the same rules as above to identify good and bad matches, all the potential stratigraphic and mineral matches were determined by the program. After all stratigraphic and mineral word tuples have been evaluated by the program, a results table is generated showing the sentence, words determined to be related, and bibliographic information. These were manually examined. Good words provided a higher accuracy of extraction when found in association with a mineral and stratigraphic association. Bad words were words often found in associations that did not have a valid mineral and stratigraphic association.....32
Table 3.1: The number of times a mineral term was found within the document set is the number of "instances" found within the corpus. The number of times a mineral instance was paired with a stratigraphic unit name is deemed the number of "mineral-stratigraphic associations". Unique stratigraphic associations refers to the number of unique stratigraphic names associated with a specific mineral. Lastly, "Unique associations with age" represents the number of unique stratigraphic units that were paired with a mineral instance. Instances of mineral formulas being found within the corpus as a mineral "instance" were assigned under the corresponding mineral, however, any mineral formula instance containing "$CaSO_4$" were allocated to anhydrite due to the variation of formulas containing this string within the corpus. Gypsum was the most found mineral, followed by halite and anhydrite. $MgSO_4$ refers to all the $MgSO_4$-bearing minerals identified including hexahydrite, kieserite, and epsomite. Hand evaluated $MgSO_4$ units are located in Appendix 1, "Epsomite-Filtered".....36
Table 4.1: The amount of evaporation per timestep, where SM is the number of moles of H_2O remaining in the evaporating solution (initial = 55.55 moles in one kilogram at standard temperature and pressure). The decrease in evaporation per time step in the models with decreasing mass of water remaining ensures the timing of saturation of each phase is precisely constrained. The simulations stop after 55.15 moles of water have evaporated... 50

Figure 3.2: Phanerozoic record of the number of unique units containing halite (blue) and calcium sulfate (orange) minerals using a 1-million-year bin size. 28
Figure 3.3 : Plots showing the abundance of CaSO4-bearing units normalized to the sum of the abundance of CaSO4-bearing and halite-bearing units (i.e., RAC) binned at geologic epochs (B) and 1 Myr intervals (A). The average of the bootstrap results is shown in red and the bounds of 60% of the data is in blue. 31
Figure 3.4: Plots showing temporal distribution of unique $CaSO_4$ occurrences throughout the

Phanerozoic binned at 1-million-year time intervals from Macrostrat. 33
Figure 3.5: The abundance of North American Phanerozoic calcium sulfate evaporites obtained from Part A shows the relative number of occurrences of $CaSO_4$ in comparison to marine carbonate binned in 1-million-year intervals; B shows the volume $CaSO_4$ evaporites found in rocks of any given age; C shows the volume of $CaSO_4$ evaporites normalized to the volume of marine carbonate in 1-million-year intervals. 35
Figure 3.6: Plot showing the ratio of the area of all dolomite bearing columns within the Macrostrat database of a given age to the area of all carbonates of the same age using 1-million-year time increments. 36
Figure 4.1: Model validation using published PHREEQC results from Blättler et al. (2020). (A) My results for degree of evaporation at gypsum saturation are plotted on y-axis and the x-axis shows the results from Blättler et al. (2020). Line of best fit in orange, and the one-to-one line is in green. (B) Histogram showing the residual differences defined as between my results minus the results from Blättler et al. (2020). Most of my results are less than 0.5 units greater. 39
Figure 4.2: The product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ in the starting solution, which varies solely through changing $[Ca^{2+}]$, plotted against the degree of evaporation at which gypsum begins to form. The inset shows the degree of evaporation at which halite forms within this experiment plotted against the same x-axis limits as in the larger plot (note the expanded scale). 45
Figure 4.3: The product of $[Ca^{2+}][SO_4^{2-}]$ in the starting solution plotted against the degree of evaporation at which gypsum begins to form from solution while $[SO_4^{2-}]$ is varied at constant Ca^{2+} (10.3 mmol kg^{-1}). The inset shows the of the degree of evaporation at which halite forms within this experiment plotted on the same axes (note the expanded y-scale). 47
Figure 4.4: The degree of evaporation at which halite and gypsum form are shown against salinity of the starting solution. The degree of evaporation for gypsum formation does not change significantly in comparison to the degree of saturation required to form halite at a given salinity. It should be noted salinity is increased by approximately 25% however the degree of evaporation required to form halite only decreases by roughly 6%. 48
Figure 4.5: Figure showing: (a) various observational estimates of paleo-pCO_2, (b) a "best-estimate" (black line) and uncertainties (grey bars) and (c) number of data used to produce these estimates (from Royer et al., 2004). Parts (a) and (b) both show model estimates from GEOCARB III in orange……59
Figure 4.6: (A) The amount of gypsum formed from batch reaction experiments where $[SO_4^{2-}] > [Ca^{2+}]$ in the initial solution (i.e., using modern seawater composition; Table 4.2). As pCO_2 increases there is less gypsum formed (22.4% decrease). Increasing pCO_2 within ranges possible in the Phanerozoic caused the total amount of gypsum to precipitate to be approximately 20% less than when pCO_2 was lower. **(B)** The degree of evaporation at the onset of gypsum precipitation from the same batch evaporation experiment shown in**.** The inset plots shows the same things but for halite. As pCO_2 increases gypsum precipitation occurs later in the experiment relative to experiments with lower pCO_2 values 52
Figure 4.7: (A) The amount of gypsum formed from batch reaction experiments where $[SO_4^{2-}] < [Ca^{2+}]$ in the initial solution (Table 4.2). As pCO_2 increases there is no increase in the amount of carbonate or gypsum formed throughout the experiments. (B) The degree of evaporation at the onset of gypsum precipitation from the batch evaporation experiment shown in part, the inset plot shows the degree of evaporation at halite saturation doesn't change across these experiments. As pCO_2 increases there is no effect on gypsum saturation from varying pCO_2 when calcium concentrations are greater than sulfate. .. 53
Figure 5.1: Plots showing the quantitative estimate of seawater chemistry and RAC throughout the Phanerozoic. (TOP) 5.1A Shows Sulfate and Calcium concentrations in mmol/L obtained through fluid inclusion analysis through Phanerozoic. (BOTTOM) 5.1B Shows the RAC through Phanerozoic with the fluid inclusion analysis of Lowenstein et al., 2003 overlain to show how this record could be used to infer calcium or sulfate concentrations in fluid inclusion analyses. Note that arrows plotted on 5.1A are qualitative estimates as to how the RAC could help constrain estimates of fluid inclusion data by narrowing the range of the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ and should be considered approximate. 62

These are two methods of determining the relative coverage of submerged preserved sediments to exposed crust. 5.2B shows the occurrence of $MgSO_4$ and KCl throughout the Phanerozoic compiled from the GDD document set (RIGHT)..... 64

ACKNOWLEDGEMENTS

I would like to thank:

Jon Husson and **Laurence Coogan** for their help over the years. This thesis would not have been possible without them, their patience, and advice over the years.

Chapter 1 Introduction

Understanding past chemical compositions of the oceans is key in developing an understanding of how Earth systems function and the main controls on the major ion composition of seawater during the Phanerozoic. Constraints on past states of the ocean are essential to provide insight into the history of Earth's surface, responses to atmospheric change, and the evolution of life. Previous studies of changes in seawater composition have led to an improved understanding of how the Earth operates as a system. Over the Phanerozoic Eon (the previous ~542 million years (Myr.)), numerous proxies argue for long term cyclic changes (every ~250 Myr.) in the major ion composition of seawater, including variation in the mineralogy of limestones and evaporites. These cycles are linked to icehouse-greenhouse cycles as well as supercontinent assembly. Interpreting records of paleoseawater chemistry requires innovative approaches to collect and analyze data from Earth history. Quantitative models allow for the assessment of the major controls on seawater chemistry. A better understanding of the co-evolution of ocean chemistry and life on Earth may also help in finding life beyond this planet, understanding how planetary oceans evolve and their role in the formation of a habitable planet (Leger et al., 2004; Madhusudhan et al., 2016).

The chemical history of seawater is important given the ocean's fundamental role in shaping our planet biologically, geologically, and geochemically. Currently, the ocean covers 71% of the Earth's surface and plays an important role in various geochemical cycles (Amante and Eakins, 2009). Processes such as dolomitization, volcanic activity and oxygenation of the atmosphere are hypothesized to have significantly influenced the evolution of the paleo-ocean's chemical state (Hardie, 1996; Horita et al., 2001; Berner, 1978). Quantitative constraints on the role of these processes are often estimated from proxies of paleo-ocean chemistry. Several proxies exist for estimating the major ion composition (Ca^{2+}, Mg^{2+}, K^{+}, Na^{+}, SO_4^{2-} and Cl^{-}) of paleo-oceans (Lowenstein et al., 2014; Horita et al., 2002). Sedimentary compilations have proven useful in investigating sedimentation changes, sea-level variation and total ocean salinity throughout the Phanerozoic (Zharkov, 1978; Ronov et al.,

1984; Hay et al., 2006; Peters and Husson, 2017). Specifically, Phanerozoic records of marine evaporites, preservation style and mineralogy of ooids in carbonate rocks, and the composition of fluid inclusions trapped in halite have been interpreted to reflect changes in major ion composition of the oceans (Hardie, 1996; Horita et al., 2001; Berner, 1978).

1.1 Sources of information about paleo-seawater chemistry

Paleoseawater chemistry has been reconstructed using a multitude of proxies to infer the composition of paleoseawater throughout the Phanerozoic. Perhaps the simplest method is using the abundance of evaporite minerals preserved in the sedimentary record. This provides information about the relative proportion of ions in seawater at the time the evaporite formed, as this controls which minerals form and in what order during evaporation. However, inputs other than seawater into evaporitic basins can modify the composition of the water away from that of seawater, and so only basins where such effects are small can be used. In recent years advances in geochemical methods have allowed the use of more advanced analysis when evaluating the composition of paleoseawater. These methods will be discussed in the following sections.

1.1.1 Formation of Evaporites and Interpreting Paleo-seawater Chemistry

One of the most detailed sources of information about paleo-ocean composition is the sedimentary record of marine evaporites. Evaporites are a type of sedimentary deposit consisting of highly soluble salts formed due to the evaporation of natural waters (Babel and Schreiber, 2014). The minerals found in evaporite deposits are controlled by the concentrations of the major ions dissolved in the evaporating solution. Evaporite deposits can form in several different environments such as evaporative continental margins, in lagoons, and continental lakes (Babel and Schreiber, 2014). Broadly, there are two distinct types of evaporite deposits. Marine evaporites have a mineralogy significantly influenced by the composition of seawater. By contrast, non-marine evaporites are formed from the evaporation of waters with no influence from seawater. Generally, modern marine evaporites follow a distinct order of mineral appearance determined by relative ionic

proportions of the ions that make up the minerals in seawater. The typical order of precipitation of evaporite minerals are calcium carbonate ($CaCO_3$), followed by calcium sulfate ($CaSO_4$), then halite (NaCl), then epsomite ($MgSO_4 \cdot 7H_2O$), and carnallite ($KCl\text{-}MgCl_2 \cdot 6(H_2O)$) (Warren, 2006).

It is, however, rare that an evaporite deposit is only influenced by the composition of the evaporating water. In the formation of an evaporite basin, several factors are important. Forming an evaporite deposit generally requires a negative water budget, in which net evaporation is greater than net water input. Evaporation is influenced by variables such as temperature, humidity, and wind speed. Depending on the evaporation rate, relative sea-level change, and total basin volume, deposits can form relatively quickly, such as the Zechstein Supergroup (Z1), a Permian evaporite, which is thought to have formed in ~4 million years and covers >100,000 km^2 (Babel and Schreiber, 2014). Marine evaporite basin are almost always found in marginal (continental) settings, meaning that they will be influenced by non-marine waters (Hardie, 1984; Babel and Schrieber, 2014; Lowenstein et al., 2014). In the case of a marginal marine basin, there are influxes of meteoric, ground, and stream waters which can alter the ionic composition of basin waters and thus affect the evaporite minerals forming in the basin. As a summary, a conceptual model from Babel and Schreiber (2014) outlines three types of basins that permit the formation of evaporite minerals. These basin types consist of lagoon, saline basin, and saline lake (Figure 1.1).

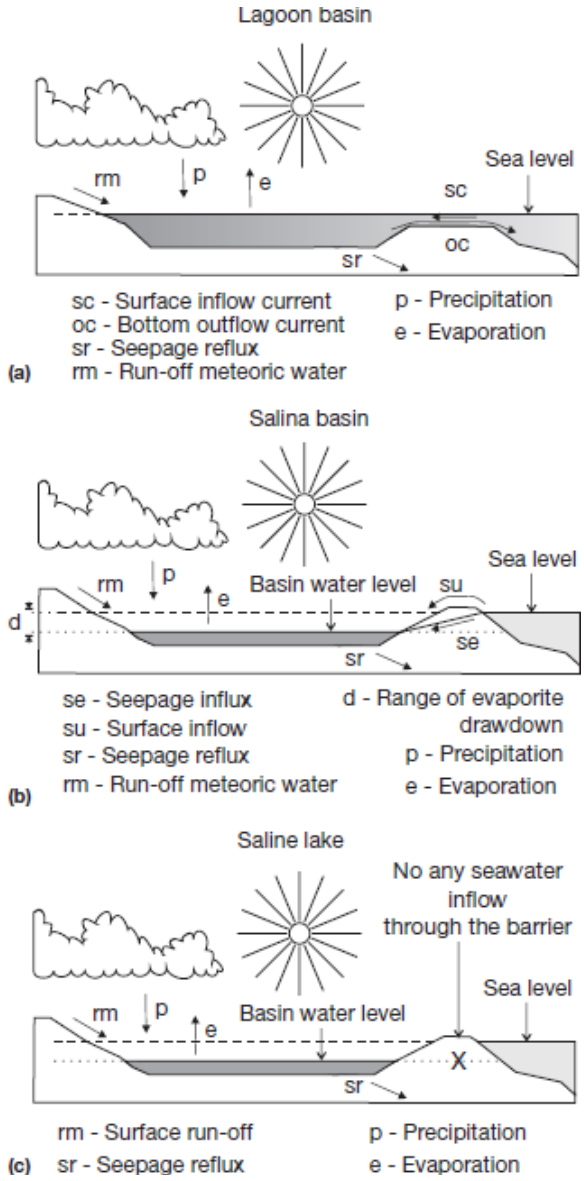

Figure 1.1: A diagram explaining the conceptual evaporite forming basin. (A) and (B) have a seawater input of water and ions through surface inflow or seepage influx, whereas (C) has no connection to seawater. Figure taken from Babel and Schreiber, (2014).

Each type of evaporite-forming basin differs from others based upon its degree of connection to the open ocean and also the sources and sinks of water for the basin. A lagoon has a direct connection to seawater and evaporite minerals can form in lagoons along shallow margins with inputs from stream water or meteoric waters as well as seawater water. Saline basins are flooded periodically or fed seawater through a permeable boundary but also fed water from rivers and rain. Saline lakes have no

input from seawater and are an example of a non-marine evaporite. During a sea-level fall, an evaporite basin can evolve between being a lagoon, a saline basin, and a saline lake stage eventually being completely isolated from the global ocean (Babel and Schreiber, 2014). Therefore, it is possible a marine basin can evolve into a continental basin within a few thousands to a few million years (Trudgill et al., 2011) depending on the main driver of sea level change (e.g., glacio-eustatic or tectonic).

Continental evaporites form in a similar fashion to marine evaporites, except that they have no seawater input. The water budget of a continental evaporite basin consists of inputs of groundwater, stream water, and meteoric water at a rate that is generally less than the total rate of water evaporation from the basin (Figure 1.1C). Distinguishing between evaporites formed in continental and marine basins is fundamental in evaluating which deposits will yield information about paleo-seawater chemistry. This can be done using paleontological, sedimentary, geochemical and mineralogical evidence.

Paleontological analysis can be used to determine if there are marine fauna adjacent to or within the evaporite unit and hence if it formed in a marine environment. However, depending on the stratigraphic distribution of paleontological data, this can be problematic, because basins can evolve from marine to non-marine over time. With little fossil preservation after gypsum formation, the use of marine fossils can be limited in abundance due to ecological limitations in hypersaline environments, generally prior to the formation halite and K-Mg salts (Babel and Schreiber, 2014). Hypersaline environments generally are not conducive to marine life, therefore marine organisms are generally not going to be found within these environments (Röthig et al., 2023).

Geochemical signatures often provide the most reliable information about the origin of source water for an evaporite deposit. Various isotope signatures ($\delta^{18}O$, $\delta^{34}S$, and $^{87}Sr/^{86}Sr$) are useful for assessing the origin of in-flowing waters (Babel and Schreiber, 2014). The $\delta^{34}S$ and $^{87}Sr/^{86}Sr$ composition of evaporites are useful because these can be compared to other records of paleoseawater's S and Sr isotopic compositions to test whether the evaporite minerals formed from seawater (Babel and Schreiber, 2014).

Distinguishing marine from non-marine evaporites based on mineralogy alone is extremely difficult (Babel and Schreiber, 2014). Ionic compositions of a continental lake can be similar to

that of seawater, and hence many of the same phases can precipitate in both localities such as gypsum and halite (Hardie, 1990). However, there are a few minerals that are exclusively found in continental settings, such as sodium carbonates, borates, and lithium bearing salts and the occurrence of these minerals indicates an evaporite deposit is not marine in origin (Table 1.1, Smoot and Lowenstein, 1991).

1.1.2 Evaporite mineralogy across the Phanerozoic

Only a few major evaporite minerals are found in Phanerozoic deposits. Volumetrically, the most important deposits consist of gypsum ($CaSO_4 * H_2O$), anhydrite ($CaSO_4$) and halite (NaCl) which are estimated to make up roughly 90% of the mass of all evaporite minerals deposited within the past 600 Myr. (Warren, 2006; Babel and Schreiber, 2014). Since the ions composing these phases are the most abundant in Phanerozoic evaporite deposits, it is thought the concentrations of the major ions in seawater have not varied dramatically from that of today ($Na^+ > Mg^{2+} \geq Ca^{2+} \geq K^+$ and $Cl^- > SO_4^{2-}, HCO_3^-$) . Despite the abundance of anhydrite, gypsum and halite, several other evaporite minerals exist and are found in many locations throughout the world (Table 1.1).

Table 1.1
Evaporite and Salt Minerals and their Chemical Formulas

Chlorides		**Sulfates**	
Halite	$NaCl$	Anhydrite	$CaSO_4$
Sylvite	KCl	Bassanite	$CaSO_4 \cdot 0.5H_2O$
Hydrohalite	$NaCl \cdot 2H_2O$	Gypsum	$CaSO_4 \cdot 2H_2O$
Bischofite	$MgCl_2 \cdot 6H_2O$	Kieserite	$MgSO_4 \cdot H_2O$
Antarciticite	$CaCl_2 \cdot 6H_2O$	Sanderite	$MgSO_4 \cdot 2H_2O$
Carnallite	$KCl \cdot MgCl_2 \cdot 6H_2O$	Leonhardite	$MgSO_4 \cdot 4H_2O$
Tachyhydrite	$CaCl_2 \cdot 2MgCl_2 \cdot 12H_2O$	Pentahydrite	$MgSO_4 \cdot 5H_2O$
Rhinneite	$FeCl_2 \cdot KCl \cdot NaCl$	Hexahydrite	$MgSO_4 \cdot 6H_2O$
Kainite	$4KCl \cdot 4MgSO_4 \cdot 11H_2O$	Epsomite	$MgSO_4 \cdot 7H_2O$
Carbonates		Vanthoffite	$3Na_2SO_4 \cdot MgSO_4$
Aragonite, Calcite	$CaCO_3$	Bloedite	$Na_2SO_4 \cdot MgSO_4 \cdot 4H_2O$
Natron	$Na_2CO_3 \cdot 10H_2O$	Loeweite	$2Na_2SO_4 \cdot 2MgSO_4 \cdot 5H_2O$
Nahcolite	$NaHCO_3$	Langbeinite	$K_2SO_4 \cdot 2MgSO_4$
Dolomite	$CaCO_3 \cdot MgCO_3$	Leonite	$K_2SO_4 \cdot 2MgSO_4$
Hunite	$CaCO_3 \cdot 3MgCO_3$	Syngenite	$K_2SO_4 \cdot CaSO_4 \cdot H_2O$
Trona	$NaHCO_3 \cdot Na_2CO_3 \cdot 2H_2O$	Polyhalite	$K_2SO_4 \cdot MgSO_4 \cdot 2CaSO_4 \cdot 2H_2O$

Table 1.1: List of evaporite minerals and their chemical formulas by evaporite mineral group (from Table 2 in Babel and Schreiber, 2014)

Changes of the mineralogy of evaporites over Earth history have been suggested to reflect changes in the major ion composition of paleo-seawater. Hardie (1996) reported distinct peaks in the frequency of occurrence of $MgSO_4$ salt deposits, which were interpreted as reflective of changing seawater chemistry (Figure 1.2). This is based upon the analysis of 34 units outlined in Zharkov's (1974) compilation of Paleozoic evaporite deposits. These $MgSO_4$ salts (largely epsomite) are found in various Phanerozoic evaporite deposits and are thought to have formed from the evaporation of seawater with a composition similar to that of modern seawater. Geologic time intervals where there are relatively high abundances of epsomite correlate with times when

aragonitic ooids, or pseudomorphs after them, are found in the geological record. Unfortunately, there are no modern analogs of $MgSO_4$ forming marine evaporites.

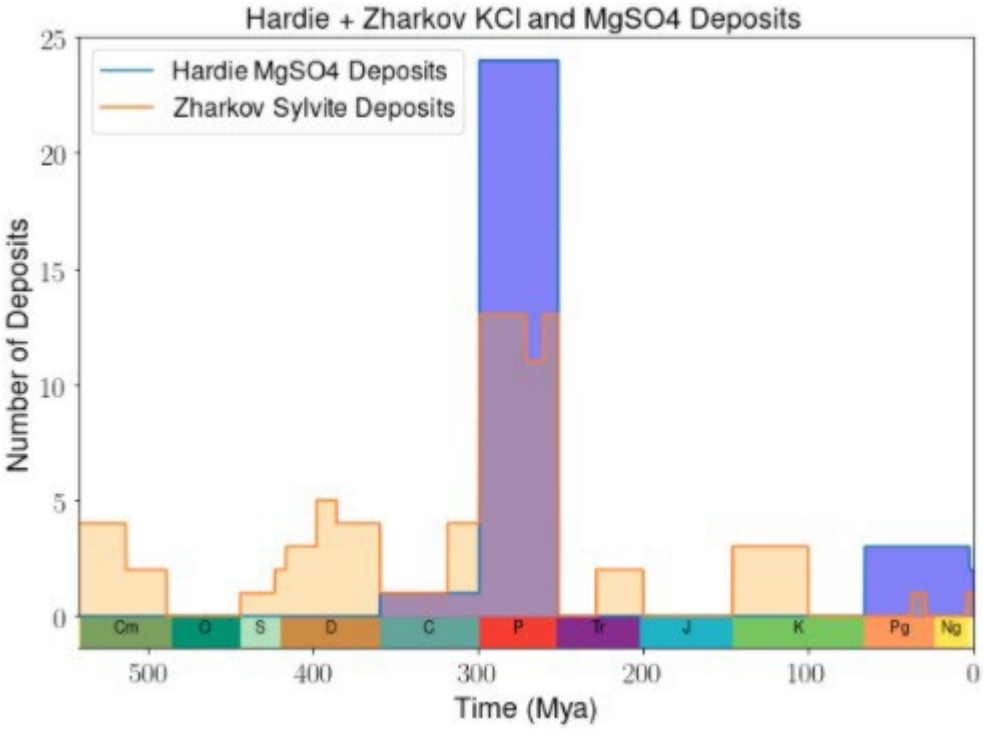

Figure 1.2: Phanerozic record of $MgSO_4$ evaporite deposits. Data from Hardie (1996) and Zharkov (1974).

1.1.3 Fluid Inclusions in evaporitic halite

Analysis of fluid inclusions preserved within marine halite deposits yields important information about paleo-seawater compositions (Timofeeff et al., 2001, Lowenstein et al., 2003, Horita et al., 2001). The water in these inclusions had been concentrated to halite saturation, and therefore do not have the major ion composition of paleo-seawater due to both evaporative concentration and mineral precipitation (such as $CaSO_4$). Therefore, several conditions or assumptions are required to relate their composition to that of paleo-seawater (Timofeeff et al., 2001). First, the halite that bears fluid inclusions must be found stratigraphically above a gypsum or anhydrite unit. Second, the halite deposit must not exhibit textures of dissolution, as interactions

with groundwater can alter the composition of the inclusions. The concentration of highly soluble elements such as Br^- or K^+ are useful for tracking degree of evaporation. Assuming that the concentration of K in seawater has been constant at 10 mM, the degree of evaporation can be estimated from the K concentration in the inclusion, and this can be used in the back calculation of paleo-seawater from which the evaporite was derived. Due to gypsum precipitation prior to halite precipitation, only either [Ca^{2+}] or [SO_4^{2-}] can be calculated, with the other generally estimated based on the assumption that the product of the Ca^{2+} and SO_4^{2-} ion concentrations has remained within 150 mM^2 of the modern value (300 mM^2) throughout the Phanerozoic (Holland and Zimmerman, 2000; Lowenstein et al., 2003). Although sparse, these fluid inclusion analyses provide constraints on seawater composition throughout the Phanerozoic (Figure 1.3).

1.2 Changes in the Phanerozoic carbonate rock record

Since the early 1980's, the major ion composition of Phanerozoic oceans has been hypothesized to have changed based on observations of oscillations in the dominant inferred mineralogy of carbonate ooids and non-skeletal cements (Sandberg, 1983). A threshold value of Mg/Ca ratio of 2 provides a rough segregation of low-Mg (Mg/Ca < 2) calcite from which aragonite or high Mg-carbonate are formed (Mg/Ca > 2) (Figure 1.3). This threshold has been hypothesized to control the variation of low Mg-calcite and high Mg-calcite preserved in the sedimentary record throughout the Phanerozoic. The emergence of carbonate-mineralizing organisms and their skeletal composition shows a general consistency with paleoseawater Mg/Ca derived from fluid inclusions (Porter, 2007). Several models have attributed changes in paleo-seawater Mg/Ca to geologic processes such as mid-ocean ridge activity or dolomitization (Hardie, 1996; Berner, 1985). These modeling attempts have been utilized to consider various drivers of changes in seawater chemistry evident in evaporites and carbonate sediments.

Carbonates are found in deep sea pelagic sediments and in shallow marine environments, preferentially at low latitudes (Warren, 2000). Sedimentary compilations show a secular variation in non-skeletal carbonate mineralogy throughout the Phanerozoic (Figure 1.3) (Sandberg, 1983). There are distinct intervals in which calcite is the dominant carbonate cement whereas other geologic time periods aragonite dominant cements are observed (Figure 1.3). These periods are

known as aragonite and calcite seas and are defined by the dominant cement found of that age.

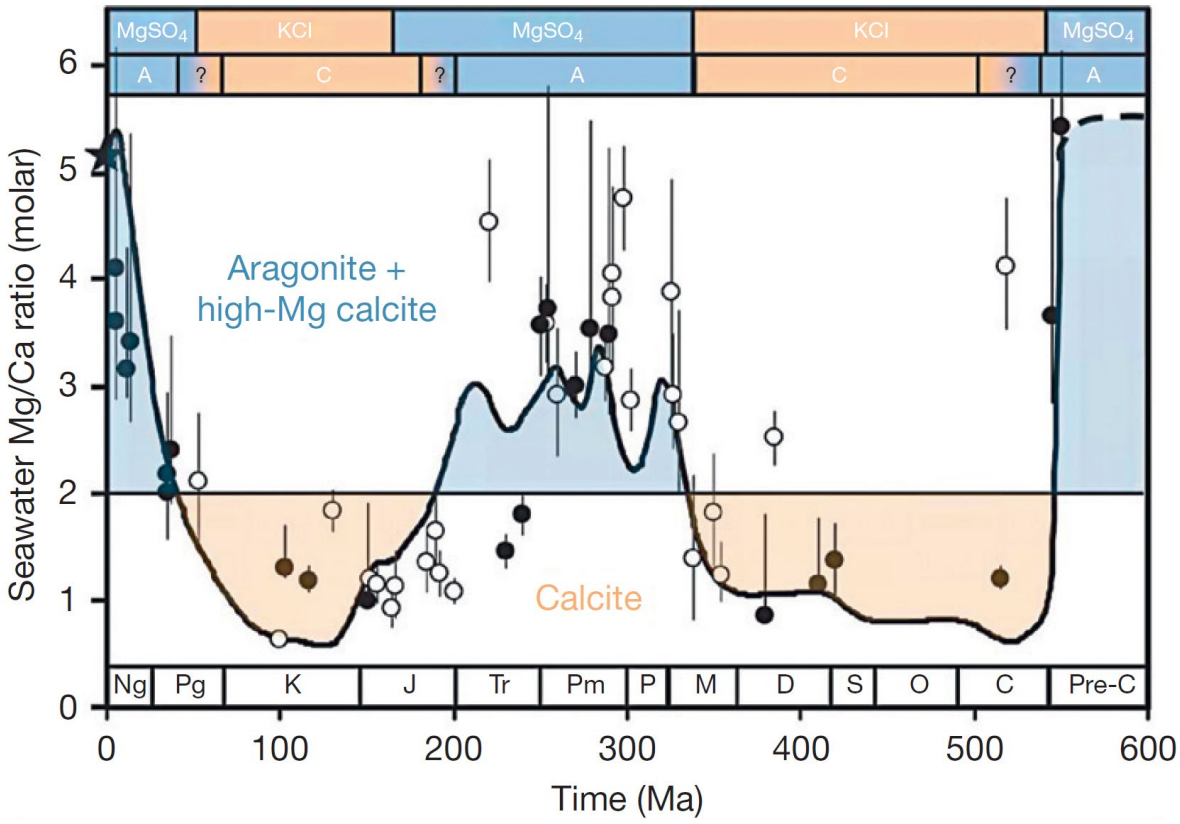

Figure 1.3: Plot showing the Mg^{2+} [Mol]/Ca^{2+} [Mol] ratio of seawater throughout the Phanerozoic based on measurements of fluid inclusion compositions. Circular markers on plot denote fluid inclusion derived concentrations. Star denotes modern seawater Mg/Ca ratio. Alternating states of calcite and aragonite seas outlined by the orange and blue segments on the top of the figure. Fluid inclusion data plotted are from (Brennan and Lowenstein 202; Brennan et al., 2004; Horita et al., 2002; Lowenstein et al., 2001, 2003, 2005; Timofeeff et al., 2006).

A related line of evidence about changes in seawater major ion composition comes from the timing of first appearance of organisms that biomineralize calcite versus aragonite (Fig. 1.4). If an organism first appears in a so-called calcite sea, it has the tendency to produce a calcite shell; the equivalent is true for aragonite seas and aragonite shells. This secular variations in the mineralogy of carbonate precipitating organisms suggest that changes in paleo-seawater compositions were important in controlling what polymorph of $CaCO_3$ organisms biomineralize (Porter, 2007; Dijk et al., 2016, Bottrell and Newton 2006).

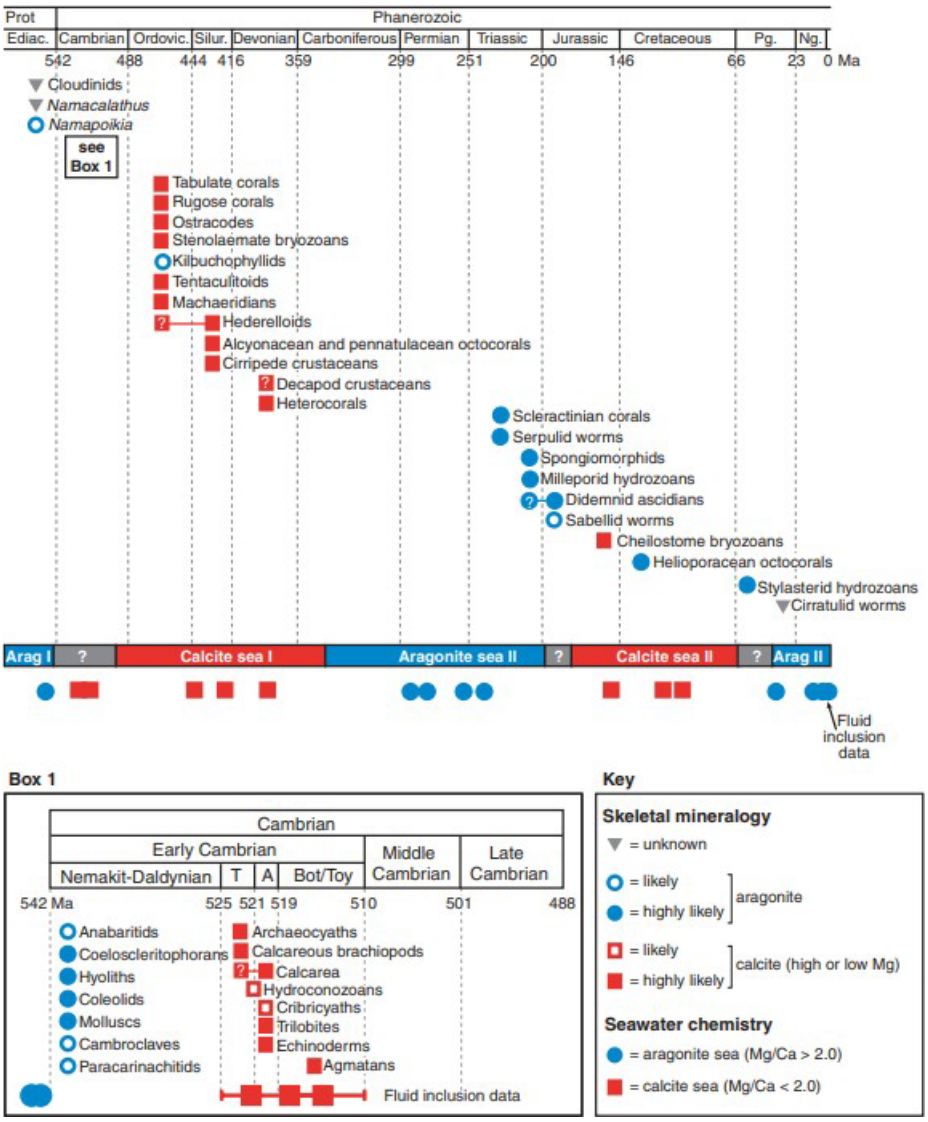

Figure 1.4: Plot showing first appearance of various carbonate-shelled taxa. Red corresponds with calcite secreting organisms whereas blue corresponds with aragonite producers. Figure obtained from Porter (2007).

Although there are oscillations in the mineralogy of carbonate cement, approximately 50% of all carbonates on Earth consist of dolomite ($(Ca,Mg)CO_3$) (Warren, 2000; Sandberg 1983). Despite the large proportion of carbonates made up of dolomite, there is little understanding of how it formed. Little dolomite is forming in modern tropical environments raising questions as to the history of dolomite and how it formed in such large quantities throughout geologic history (Warren, 2000). Discrepancies between the amount of dolomite forming today versus the amount formed in the past is known as the "dolomite-problem" (Arvidson and Mackenzie, 1999).

Several hypotheses exist to explain the variation in Mg/Ca ratio of seawater over the Phanerozoic. One hypothesis involves variations in the alteration of seafloor basalts due to changes in the rate of crustal accretion along mid-ocean ridges (Holland and Zimmermann, 2000). Mid-ocean ridges are hypothesized to significantly influence the Mg/Ca of seawater (Hardie, 1996). Basalt-seawater reaction leads to removal of Mg^{2+} from seawater and addition of Ca^{2+}. Thus, during periods of low rates of crustal accretion, when less seawater is hydrothermally altered, the Mg/Ca ratio in seawater is expected to increase. Periods of higher rates of crustal accretion allow for the alteration of more seawater, thus driving the Mg/Ca of seawater down.

An alternative hypothesis is that changes in the amount of dolomite formed could influence the Mg/Ca of seawater. For example, the increase in seawater Mg/Ca since 150 Mya. could be attributed to decreased dolomitization in shallow-marine carbonates. It has been shown that dolomitization may occur during periods of transgression and higher atmospheric pCO_2 (Given and Wilkinson, 1987). Additional hypotheses state a decrease in the formation of dolomite, a major sink for Mg^{2+} and alkalinity from seawater, is linked to an increase in SO_4^{2-} in the oceans, as recorded in fluid inclusion analyses, and increases in SO_4^{2-} deposition in sediments (Wortmann and Chernyavsky, 2007; Lowenstein et al., 2003; Lippmann, 1973). Experimental studies and models of dolomite formation have shown that higher concentrations of seawater SO_4^{2-}can kinetically inhibit the formation of dolomite (Baker and Kastner, 1981). Hence, increased seawater SO_4^{2-}concentrations would tend to prevent the formation of dolomite, leading to a decline in dolomite formation as SO_4^{2-} increases (Baker and Kastner, 1981) and an increase in seawater Mg/Ca.

1.3 Sulfur isotopes in Seawater

The global cycling of sulfur through Earth's surface consists of several sources and sinks. Sulfur is sourced to the oceans from volcanic activity, as juvenile sulfur or the weathering of sulfate and sulfides on the continents. The formation of evaporites and pyrite burial consume oceanic sulfate (Figure 1.5). Variations in the $\delta^{34}S$ composition of paleo-seawater could be indicative of changes in several of these processes because S buried in pyrite is strongly enriched in ^{32}S relative to sulfate in seawater or sulfate minerals. For example, increases in atmospheric oxygen could have increased the concentration of sulfate. The $\delta^{34}S$ record shows a general curve through the Phanerozoic but exhibits positive and negative excursions that are attributed to 2 main drivers. Within the context of the Phanerozoic sulfur system, two main drivers of isotopic fractionation are due to the metabolism of sulfate reducing bacteria, which prefers lighter ^{32}S isotopes, resulting in positive excursions and the oxidation or less prevalent reduction of sulfate as pyrite, resulting in a negative excursion. Positive excursions are due to the bond strength between ^{34}S and oxygen being more stable and thus more difficult to break than the bond between ^{32}S and oxygen. Therefore, positive signals in carbonate associated sulfate generally suggest that more sulfate reduction or pyrite burial must be occurring. When this record decreases, it generally is a signal that more pyrite is being weathered than buried.

Sulfate is a major ion in seawater and its global cycling is an important indication of Earth processes. Estimates of the sulfur isotopic composition of paleoseawater are often made based on measurements of S associated with marine carbonates or evaporitic gypsum; these suggest fluctuations in the sulfur cycle over the Phanerozoic. Positive excursions in the $\delta^{34}S$, are thought to be times of high pyrite burial because pyrite is depleted in ^{34}S, whereas negative excursions are thought to be

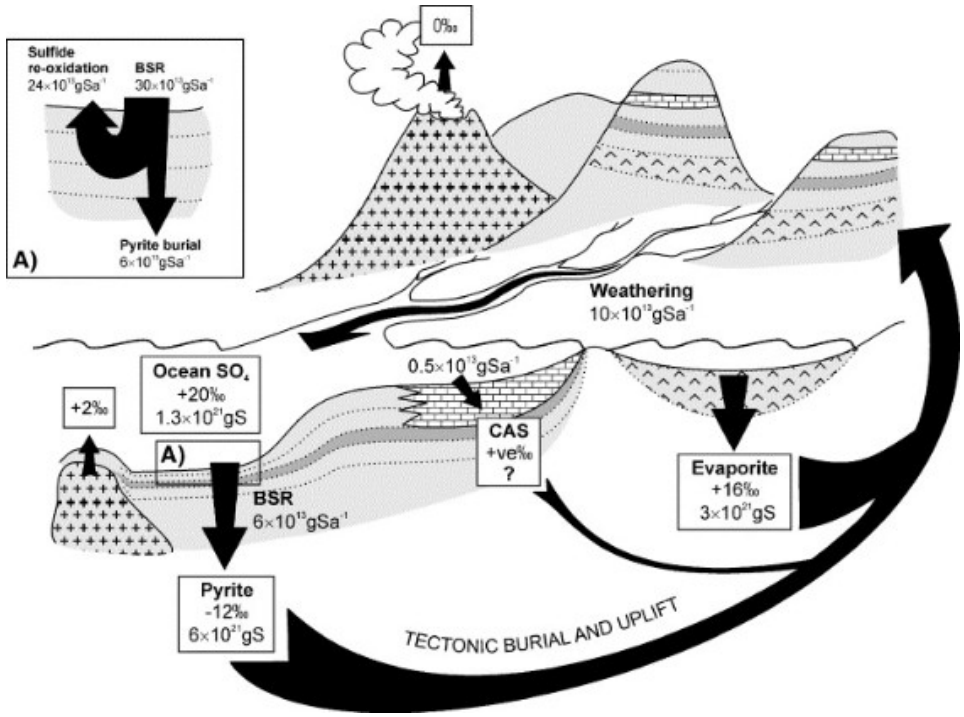

Figure 1.5: Cartoon of the global cycling of sulfur from Bottrell and Newton (2006). Sulfur is outgassed during volcanism and sourced to the ocean via precipitation as well as from weathering of sulfides and sulfates. Major sinks of sulfate from seawater include evaporite deposition, microbial sulfate reduction along marine shelves and sulfate reduction in pelagic sediments. Units of mass are grams of sulfur and units of fluxes are grams of sulfur per year.

times of high concentrations of marine sulfate (Halevy et al., 2007). Comprehensive datasets of Phanerozoic $\delta^{34}S$ indicate several changes in the sulfur cycle (Figure 1.6).

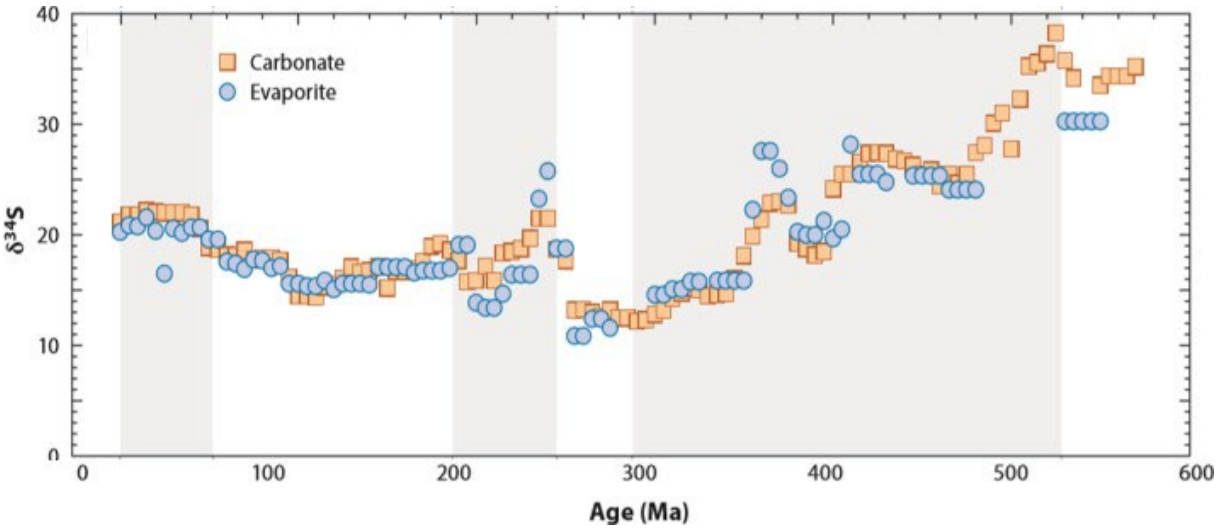

Figure 1.6: The Phanerozoic record of δ34S from carbonates and evaporites from Turchyn and DePaolo (2019).

1.4 Goals of this Research

The aim of this research was to investigate changes in paleo-seawater by analyzing the time-series variation of marine evaporite deposits and their mineralogy. Previous approaches used smaller datasets relative to the data obtained in GeoDeepDive and Macrostrat based approaches developed here. Having more data collected in an unbiased manner allows for the testing of older hypotheses against a more comprehensive dataset. First, a comprehensive record was compiled from GeoDeepDive and Macrostrat of evaporites and their mineralogy through the Phanerozoic to understand and analyze the secular variations marine evaporites. Secondly, by systematically collecting a stratigraphic unit's mineralogy and age information, I analyzed the data to determine if there were any trends indicating a change in seawater composition based upon evaporite mineral occurrences. Lastly, I developed a batch evaporation model using PHREEQC to evaluate different hypotheses about the mechanisms that drove the observed changes in the occurrence of marine evaporite minerals throughout the Phanerozoic.

Chapter 2 Methods

2.1 Macrostrat

Macrostrat is a chronostratigraphic and geospatial database that describes the basic geology of North America, the Caribbean, New Zealand, and some regions of the deep sea. Geographic regions are divided into columns, each of which consist of a set of temporally distinct geologic units that describes the surface and sub-surface geology of that region. The database was developed to aggregate geological descriptions, geological maps and chronostratigraphic columns into a description of Earth's upper crust (Peters et al., 2018) (Figure 2.1). Broadly, the spacing of geologic columns is dictated by the complexity of the geology in a given region, for example, more variability means more columns.

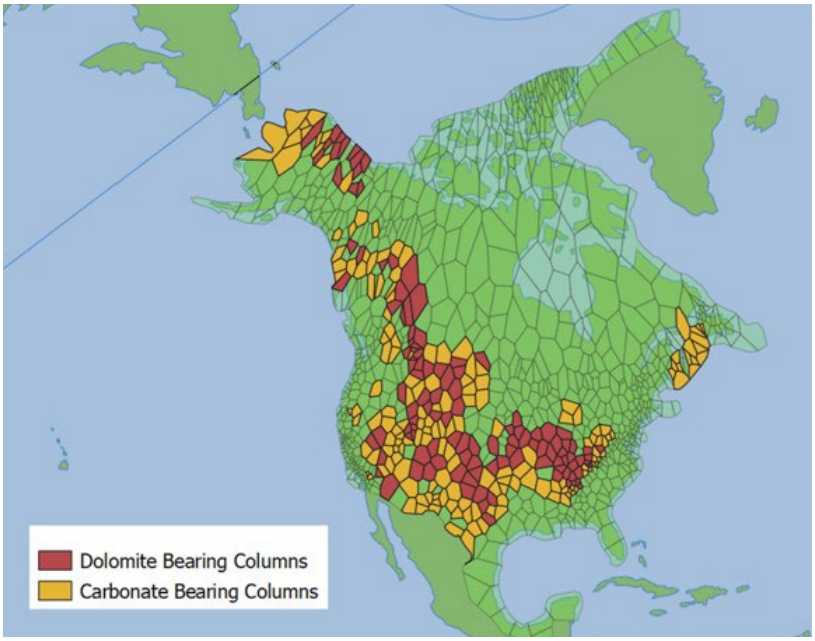

Figure 2.1: A Macrostrat map of the North American distribution of dolomite at 350 Ma. The red colored polygons represent columns that contain dolomite, yellow polygons represent columns containing only Ca-Carbonate.

These columns have been shaped into polygons determined using a Dirichlet tessellation around the geographic position of each of the 1402 chronostratigraphic columns (Meyers and Peters, 2011).

Macrostrat allows for the abundance of any given lithology to be analyzed both spatially and temporally. In this study, the Macrostrat database was used to investigate two things: the fraction of North American carbonates containing dolomite during the Phanerozoic, and to obtain ages of geologic units containing evaporite minerals. The fraction of carbonate rocks containing dolomite was derived by dividing the areal abundance (km^2) of dolomite containing polygons by the areal abundance of all carbonate-containing polygons found in North America over the past 542 Mya. This calculation was performed at 1 Myr intervals.

Analyzing the data in this way requires binning the stratigraphic units using pre-determined age bins (for example, even-sized 1 Myr. bins, or geologic periods). A given rock unit does not exist at only at one point in time, but rather has an estimated top and bottom age, between which sedimentation is considered continuous when performing this kind of analysis (Peters, 2006; Peters et al., 2017). For each age bin, each stratigraphic unit intersects that bin in 1 of 4 distinct ways (Figure 2.2): a unit can range through the top and bottom age of a bin (bt in fig 2.2), a unit's extent can be entirely contained between the top and bottom age of a bin (FL in fig 2.2), a unit can initiate within a bin and cross its top age (Ft in fig 2.2), or a unit can initiate before the age bin and truncate within it (bL in fig 2.2). This way of documenting and analyzing geologic data in time-series can be called time binning and is analogous to paleontological analysis of taxa ranges in the rock record (Foote, 2000).

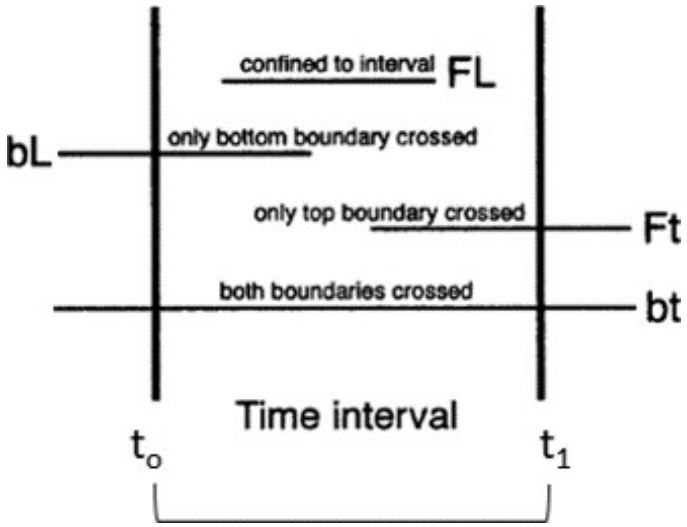

Figure 2.2: Diagram describing the four ways a geologic unit can intersect an age bin. A unit can cross either the top age (Ft) or bottom age (lb.) of a time interval. A unit can extend across the top and bottom age of a time interval (bt). Lastly, a unit can be within the top and bottom age of a time interval (FL). Figure from Peters (2006).

The Macrostrat database was also used to help in determining ages of various stratigraphic units and lithologies found by the text and data-mining program described in the following section. Names of stratigraphic units found by this program were used to search for geologic age information within Macrostrat.

2.2 GeoDeepDive and Text Mining

The GeoDeepDive (GDD) database was used to collect and analyze documents that mention evaporites. GeoDeepDive is a digital library of published scientific documents that cover a broad array of disciplines, including geology. It currently contains nearly 17 million documents parsed by CoreNLP, a natural language processing program (https://geodeepdive.org/). Natural language processing is the procedure of algorithmically parsing a sentence, mapping all grammar and word relationships within the sentence. This processing makes documents in GDD amenable to text and data mining, allowing computer programs to analyze these predetermined relationships, and identify relevant data accurately. Previous work has demonstrated that GDD analyses are useful for compilations of records of Earth History (Peters et al., 2017).

The GDD database is continuously growing in size as new papers are added hourly from

different publishing sources. Subsets of documents that are relevant to a given topic are identified via matching to key words of interest, such as evaporite minerals (Table 2.2). A total of 32,543 GDD documents matched of these keywords and were further analyzed.

Query	Terms Used	Query Size
A	Evaporite, salt, gypsum, anhydrite, halite, epsomite, potash, potash salt, k salt, sylvite, hydrohalite, bischofite, antacitite, carnallite, tachyhydrite, rhinneite, kainite, thermonatrite, soda, nahcolite, basanite, kieserite, siderite, epsomite, thernadite, mirabilite, celestine, glaserite, vanthoffitite, bleodite, loewite, langbeinite , leonine, glauberite, syngenite, polyhalite, northupite, burette, techie, hanksite, lautarite, kernite, borax, colemanite, kieserite, hexahydrite, pentahydrite, kieserite	32,543 Documents

Table 2.1: Table of terms queried and documents returned from GDD. Bibliography contained in Appendix 1.1.

2.2.1 Program Description

The goal of the data mining program I developed was to locate text descriptions of evaporites, determine their mineralogies, ages of these deposits and origin of these deposits (e.g., marine versus non-marine origin). To do this, the program published by Peters et al. (2017) to determine the distribution of stromatolites in the geological record was used as a starting point. Functionally, the program is based upon using simple logical relationships that will extract a *candidate*, which is a pairing between a mineral name and a stratigraphic name (a tuple), using information from within the document to evaluate the relationship between these two names. Evaporite mineral instances are found by searching for specific evaporite mineral names (Table 2.1). Second, all documents containing mention of one or more of the evaporite minerals listed in Table 2.1 were searched for keywords that indicate a stratigraphic name (e.g. Group, Supergroup, Formation, etc.). After such a word was found, preceding words that made up the stratigraphic name were collected. This was done by collecting capitalized words that preceded the stratigraphic keywords. In case the stratigraphic name is near the beginning of a sentence, a list of stop-words, such as “The, They, Although, Moreover” and other common words that indicate the beginning of a sentence, was used to exclude words that are not part of the name (e.g., “Bitter Springs Formation” vs “The Bitter Springs Formation”). Word position within a sentence and the part of speech

determined by NLP are also used to determine the extent of a stratigraphic name. Once a name has been found in a given document, the program searches for any informal use of stratigraphic names found in that paper (e.g., “the Bitter Springs evaporites”).

After finding the location of stratigraphic units and mineral words within a document, the relationship between the stratigraphic word and mineral word are then evaluated. This is done by considering the proximity of the mineral name to the stratigraphic name within a sentence, whether the mineral is within the stratigraphic name, or if the mineral has a direct parent/daughter relationship to the stratigraphic name determined by NLP. Phrases between the evaporite mineral and stratigraphic unit, such as “found in”, “within”, “contains”, and others (Table 2.2) within five words before or after a stratigraphic mention, were considered indications that this is a valid mineral-stratigraphic name tuple. Furthermore, if words such as “overlying”, “lacking”, “underlying”, “over”, or “under” were found between the mineral name and the stratigraphic name it was likely that the mineral stratigraphic association was comparing or contrasting adjacent lithology. Often in these instances there was indication that the mineral in reference is in an adjacent unit due to the sentence describing a section or portion of lithology and the surrounding geologic units. Overlying or underlying formations were often discussed in several papers. To account for this a logical function evaluated if there were more than two stratigraphic units within the sentence which could make it difficult to accurately map it out. Often these formations were discussed in subsequent or preceding sentences individually therefore, the candidate mineral and stratigraphic tuple was is omitted from these instances. Due to the way documents were parsed, the NLP within GeoDeepDive handles tables as if they were text within a sentence. This leads to some sentences within the database to contain table indicators or characters not found within text in scientific literature (Table 2.2). This can lead to very long sentences that can contain multiple stratigraphic names. To handle mineral and stratigraphic associations found in these cases were filtered by evaluating if the stratigraphic word and mineral word were separated by more than 40 words, had more than 7 table indicators, or the mineral was not assigned to that stratigraphic name due to a low signal to noise ratio observed in the training data (Table 2.2). Good mineral and stratigraphic associations were found parsed tables within the dataset, and a lower number of table indicators could provide data within the same row of a table, allowing that information to be extracted. These rules were developed by manually by examining

1,800 labeled mineral and stratigraphic tuples to identify the broadest and most accurate result set.

Variable	Values
Good Words	present, found, abundant, rare, within, contain, contains, includes, crystallized, from, from the, is primarily, formed by, formed, is in, form, within, precipitation, fossil, shell, organisms
Bad Words	not, does not contain, lacking, not in, does not contain, lacks, not found in, not found within, not within, absent missing, overlying, overlays, doesn't, does not include, volcanic, chemical weathering, seafloor
Table Indicators	'Table','Figure',;',':','-RRB-','-LRB-','.','the','The','. . .','...'

Table 2.2 List of variables used in the text mining program to evaluate correct and incorrect instances of mineral – stratigraphic name tuples. The same steps are taken for distant mentions that extended beyond an individual sentence of an evaporite mineral and a stratigraphic entity. This approach is used is to match minerals to units that may not have a full stratigraphic name in the text, but the root words are used in the instance. Applying the same rules as above to identify good and bad matches, all the potential stratigraphic and mineral matches were determined by the program. After all stratigraphic and mineral word tuples have been evaluated by the program, a results table is generated showing the sentence, words determined to be related, and bibliographic information. These were manually examined. Good words provided a higher accuracy of extraction when found in association with a mineral and stratigraphic association. Bad words were words often found in associations that did not have a valid mineral and stratigraphic association.

After a stratigraphic name has been assigned to an evaporite mineral, an age needs to be provided for the stratigraphic unit. First, the Macrostrat database was queried to find defined age boundaries for the unit. However, only 65% of all candidates stratigraphic names were found within the Macrostrat database. To determine the ages of the other units determined to contain evaporite minerals, a program was developed to identify and match geologic age words that describe the unit within a document.

To assign an age within the GDD document, a list of known bin names from the international geologic timescale obtained from Macrostrat were flagged within a five-word window of any stratigraphic name or root found to have a mineral associated with it. Next, several rules were used to determine if it was an accurate age. First, if any keyword of a stratigraphic unit such as: "Group",

"Member", "Bed", "Unit", "Supergroup", or any of their abbreviations was between the stratigraphic unit in question it was omitted due to the likelihood of multiple names in a sentence making it difficult to accurately assign an association. If the sentence had more than seven table indicators the age was not recorded due to the low signal to noise ratio of association found in those instances. Lastly, if the age was near to or immediately adjacent the stratigraphic name it was recorded. Some stratigraphic mentions had age information provided in Macrostrat. To provide the most accurate age information the ages for stratigraphic entities within Macrostrat were assigned first, then if no age information was available for the unit found in the data extraction, the in-text information was used to provide an age association.

Once all age – stratigraphic name tuples were found, the age terms were evaluated to check for internal consistency in the compiled age assignments across different scientific publications. If the ages found in different papers describing one stratigraphic unit were the same, then the age was determined to be accurate. If less than 75% of age words linked to a given unit overlapped with one another (e.g., Late Devonian, Famennian, Paleozoic, Ediacaran, Cryogenian), then no age was assigned this unit.

Determining origin of the evaporite deposit was the last aspect of the workflow. This was done in a similar way to finding age-unit name tuples. First, GDD documents were searched for non-marine indicator words, such as: "lake", "lacustrine", "continental", "non-marine", "playa", "alluvial fan", "hydrothermal", "chemical weathering", "volcanic", "sea floor", "lithium". The term chemical weathering was found to be associated with eolian deposition of gypsum and halite within GDD sentence sets. The terms volcanic and seafloor were found to often refer to mid ocean ridge phase associations (e.g., anhydrite). Good words consisted of: "marine", "sea water", "lagoon", "fossil", "shell", "organisms". Marine/non-marine words were mapped to stratigraphic units using NLP, word proximity, and keywords between the two to find a good match. The marine/non-marine keyword had to be within 20 words of the stratigraphic name and have no other stratigraphic names or less than 5 table indicators between them. Furthermore, if a unit was found to contain commonly non-marine evaporite minerals such as sodium carbonate, borates, or lithium salts, the unit was then considered to be non-marine. Units determined to be non-marine were omitted from further analysis.

Uncertainty in these text extractions was evaluated by reviewing 500 randomly selected results from the program. For each, I manually checked the origin of a deposit, mineralogy of a deposit, and age of the deposit using information from the document. In 89% of cases where a mineral-stratigraphic association was matched with a geologic age, the program correctly assigned the mineralogy, stratigraphic name, and geologic age. Another way uncertainty was estimated was via bootstrapping. Bootstrapping should show larger uncertainty if the deposit only is mentioned in one paper as it has a higher chance of being left out of any given bootstrap. The bootstrap approach used to evaluate the error in the text-mining results sampled the "docid" field of the results set, randomly sampled 21,432 documents allowing for replacement, and generated a synthetic results set of the mineral and stratigraphic associations found within those documents. The bootstrap was used to create 1,000 synthetic datasets to approximate error within the text-mining program. Error was evaluated by calculating the 20^{th} and 80^{th} quartiles from the average of the data result.

Chapter 3 The geological record of Phanerozoic evaporite deposits

3.1 GeoDeepDive and Macrostrat Results

As described in Chapter 2, a text-mining program was written to extract mineralogic data and descriptions from papers describing marine sedimentary deposits to characterize the mineralogy of salt bearing deposits (Section 2.2). This program was used to collect and evaluate if the mineralogical data collected from a paper was describing a marine salt deposit or a non-marine salt deposit. Using the stratigraphic name of the deposits and the Macrostrat database, ages were assigned to each unique stratigraphic name discovered by the extractor. This approach was used to describe the mineralogy of salt bearing deposits throughout the Phanerozoic (Section 2.2.1), extracting 22,083 (mineral-stratigraphic name) tuples from 21,432 documents. The results from this analysis are presented below.

3.2 KCl and $MgSO_4$ deposits

Evaporites containing KCl or $MgSO_4$-bearing minerals were documented for the Phanerozoic (Figure 3.1). There were 534 extractions that mentioned either or both of these two minerals as being present in an evaporite bearing deposit. Due to the small number of reports of these minerals, all unique associations with an assigned age containing $MgSO_4$-bearing minerals were evaluated manually (Appendix 1). Deposits that were manually evaluated as a marine occurrence of $MgSO_4$ were determined by: (i) a correct association of a stratigraphic name with an evaporite deposit with a definite geologic age, (ii) a direct description of marine deposition, and (iii) the lack of diagenetic

alteration descriptions describing the identified unit. Of the 791 results, only 303 were unique stratigraphic units with an associated age bearing KCl or $MgSO_4$. Following this evaluation, the data produced by the text mining program including the identified geologic age, marine or non-marine origin, and stratigraphic name were compiled into a time-series plot for all results mentioning either KCl or $MgSO_4$ salts. Of these 303 combined extractions KCl or $MgSO_4$, 51 unique $MgSO_4$ units and 83 unique KCl units were associated with a geologic age. (Table 3.1). When evaluating deposit origin, only 11 unique $MgSO_4$ units associated with a geologic age were definitively described as marine in origin from the supplementary text information.

Mineral	**Instances**	**Mineral Stratigraphic Associations**	**Unique Stratigraphic Associations**	**Unique Associations w/ Age**
Gypsum	57,209	6,099	1,204	630
Anhydrite	24,673	4,580	841	475
Halite	43,752	6,826	874	448
$MgSO_4$	3,542	263	104	51
Sylvite	6,941	762	199	83

Table 3.1 : The number of times a mineral term was found within the document set is the number of "instances" found within the corpus. The number of times a mineral instance was paired with a stratigraphic unit name is deemed the number of "mineral-stratigraphic associations". Unique stratigraphic associations refers to the number of unique stratigraphic names associated with a specific mineral. Lastly, "Unique associations with age" represents the number of unique stratigraphic units that were paired with a mineral instance. Instances of mineral formulas being found within the corpus as a mineral "instance" were assigned under the corresponding mineral, however, any mineral formula instance containing "$CaSO_4$" were allocated to anhydrite due to the variation of formulas containing this string within the corpus. Gypsum was the most found mineral, followed by halite and anhydrite. $MgSO_4$ refers to all the $MgSO_4$-bearing minerals identified including hexahydrite, kieserite, and epsomite. Hand evaluated $MgSO_4$ units are located in Appendix 1, "Epsomite-Filtered".

The age distribution of evaporite deposits containing $MgSO_4$ and KCl found in this work, and

those reported by Hardie (1996) and Zharkov (1974) are compared in Figure 3.1. Marine sylvite deposits recorded in Zharkov (1974) and from this work show that sylvite is a common mineral found in evaporite deposits throughout the Phanerozoic, and that sylvite bearing evaporites can overlap in age with evaporites containing $MgSO_4$-bearing minerals. (Figure 3.1). The new results show that sylvite-bearing evaporite deposits are most common in the Permian Period, which was also reported by Zharkov (1974). It is important to note that simply from the occurrence of sylvite deposits, as documented here, it is not possible to differentiate between sylvite produced by carnallite dissolution and sylvite precipitated as a primary phase.

The time-series of $MgSO_4$ evaporites produced here (Fig. 3.1) is in good agreement with the results of Hardie (1996), with $MgSO_4$-bearing evaporites occurring only during specific intervals in the Phanerozoic. However, two deposits found within GDD data are outside the age-range reported by Hardie (1996). These are from the late Devonian and the early Triassic.

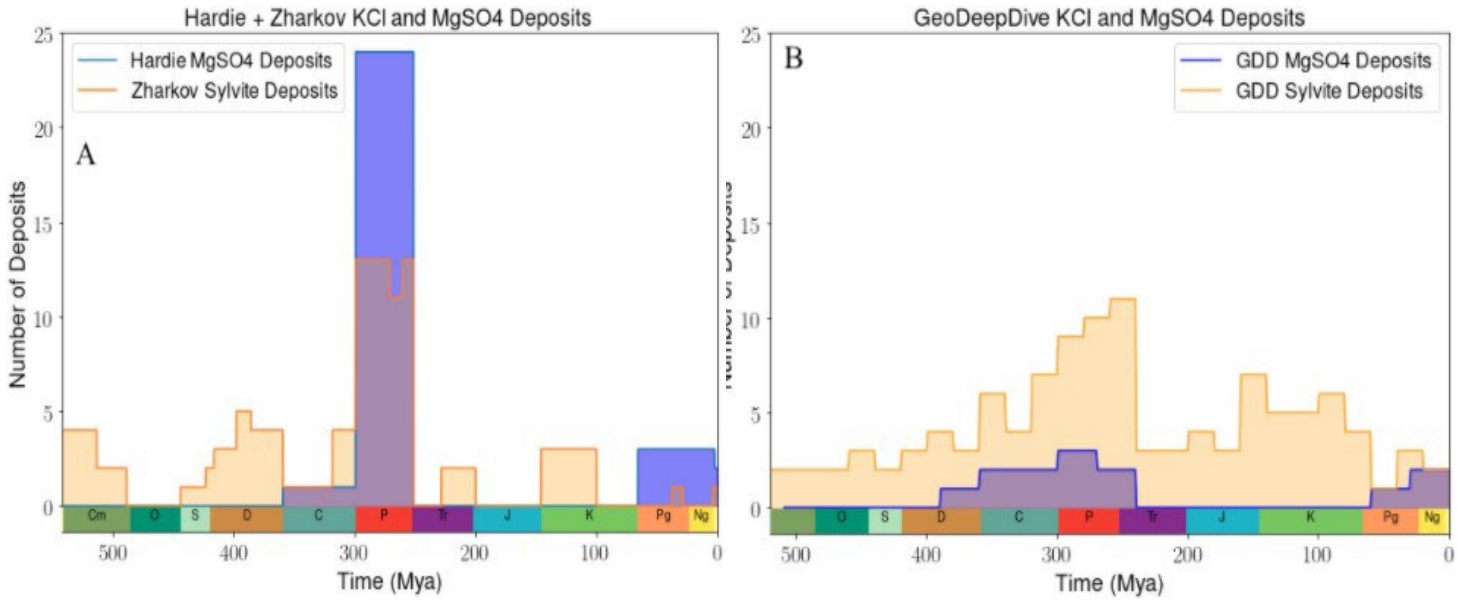

Figure 3.1: A: Phanerozoic time-series of MgSO4 bearing deposits from Hardie (1996) and sylvite-bearing evaporites reported by Zharkov (1974). B: Time-series of marine KCl and $MgSO_4$ evaporites extracted from the GeoDeepDive database in this study.

3.3 $CaSO_4$ Deposits

Of all instances describing a mineral with a stratigraphic unit associated with a geologic age, 1,544 contained either halite, anhydrite, or gypsum (Table 3.1). Gypsum is reported to occur in 448 stratigraphic units with associated age, being more commonly observed than halite (630 associations with age) and anhydrite (475 associations with age). The next most common mineral within the dataset is carnallite which is only reported in 125 stratigraphic units associated with a geologic age. The largest number of units containing gypsum, halite, anhydrite, and many other evaporite minerals formed during the late Permian. To illustrate the relative occurrence of evaporite deposits during the Phanerozoic, halite, gypsum, and anhydrite are plotted in a time-series in 1-million-year intervals (Figure 3.2). This shows the number of deposits containing each mineral that intersect in age with each 1 Myr interval.

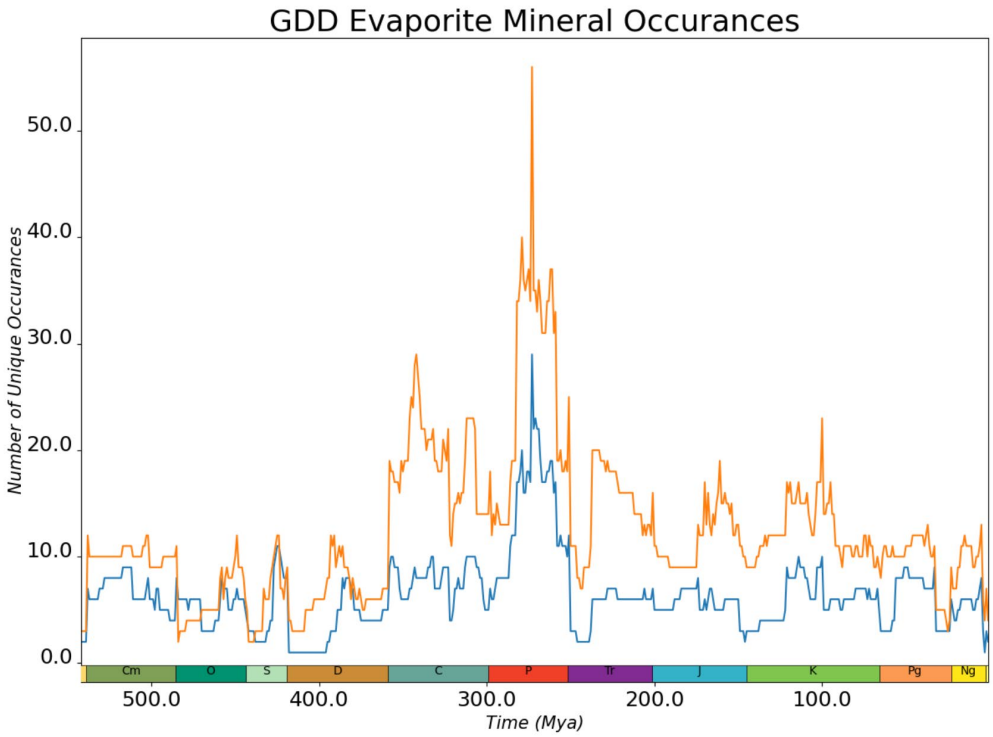

Figure 3.2: Phanerozoic record of the number of unique units containing halite (blue) and calcium sulfate (orange) minerals using

a 1-million-year bin size.

Since one of the largest sinks of SO_4^{2-} from seawater is $CaSO_4$ precipitation, the temporal distribution of $CaSO_4$-bearing evaporites, and the abundance of $CaSO_4$-bearing units relative to the abundance of halite bearing units is described next. The relative occurrence of calcium sulfate (RAC) was determined by normalizing the number of unique evaporites that contain gypsum and/or anhydrite (i.e., a $CaSO_4$ mineral) at a given time to the sum of the number of unique evaporites that contain halite and the number of unique evaporites that contain either calcium sulfate mineral during the same time interval. This approach was used based on the assumption that the record of halite-bearing evaporites simply tracks the occurrence of conditions appropriate for evaporite deposit formation (and preservation); i.e., assuming that this does not vary substantially due to changes in seawater Na^+ and Cl^- concentrations over the Phanerozoic. While small changes in Na^+ and Cl^- concentrations are likely to have occurred (Hay et al., 2006), these are generally thought to have been small relative to the changes in concentration of $Ca^{2+}$and SO_4^{2-}. The relative occurrence of calcium sulfate is thus calculated:

$$\mathrm{RAC} = \sum_x^n \mathrm{CSD} / \left(\sum_x^n \mathrm{CSD} + \sum_x^n \mathrm{HD} \right) \qquad \text{Eq. 3.1}$$

Where RAC is the relative abundance of calcium sulfate evaporites occurring within between times x and n, CSD is unique calcium sulfate evaporites from a given time interval, HD is unique halite bearing evaporites from the same time interval.

The results shown on Figure 3.3 are the bootstrapped approximation of RAC binned in 1-million-year time bins (Figure 3.3A) and international epochs (Figure 3.3B). The uncertainty shown on the results is approximated by showing the 20th and 80th quartiles from a bootstrap. This was performed by randomly selecting the documents, with replacement, within the results obtained from the GDD document set for each trial and tabulating the mineral occurrences found therein

(Figure 3.3). The uncertainty observed within the bootstrap attempts was determined to be sufficiently precise after 1,000 random trials.

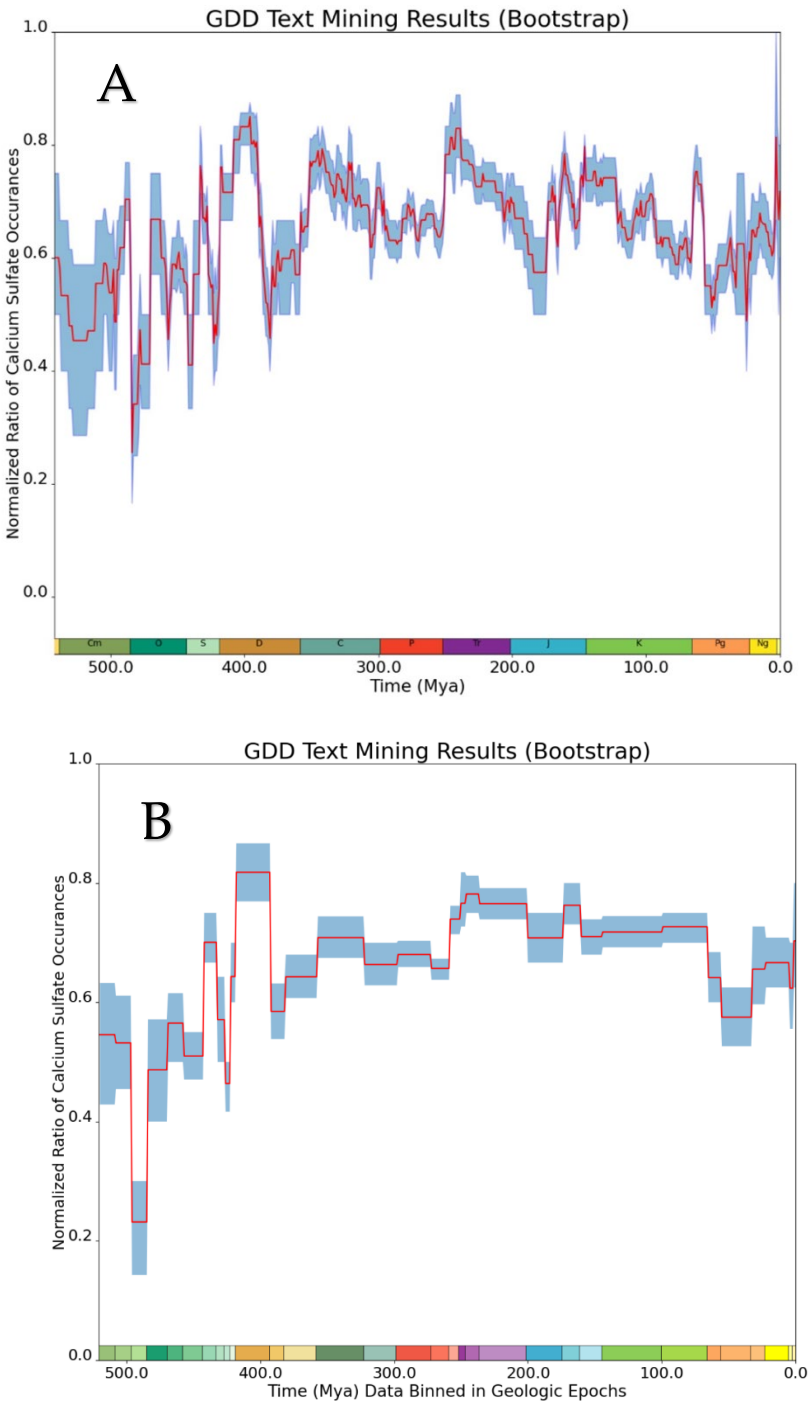

Figure 3.3 : Plots showing the abundance of $CaSO_4$-bearing units normalized to the sum of the abundance of $CaSO_4$-bearing and halite-bearing units (i.e., RAC) binned at geologic epochs (B) and 1 Myr intervals (A). The average of the bootstrap results is shown in red and the bounds of 60% of the data is in blue.

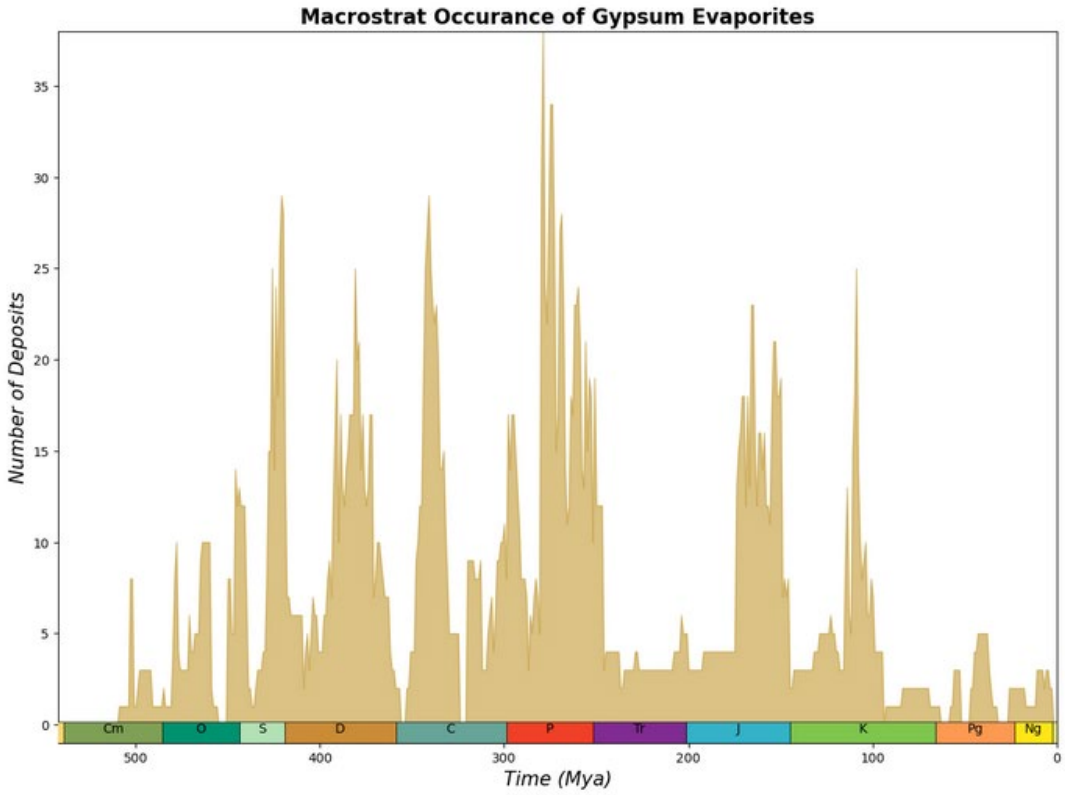
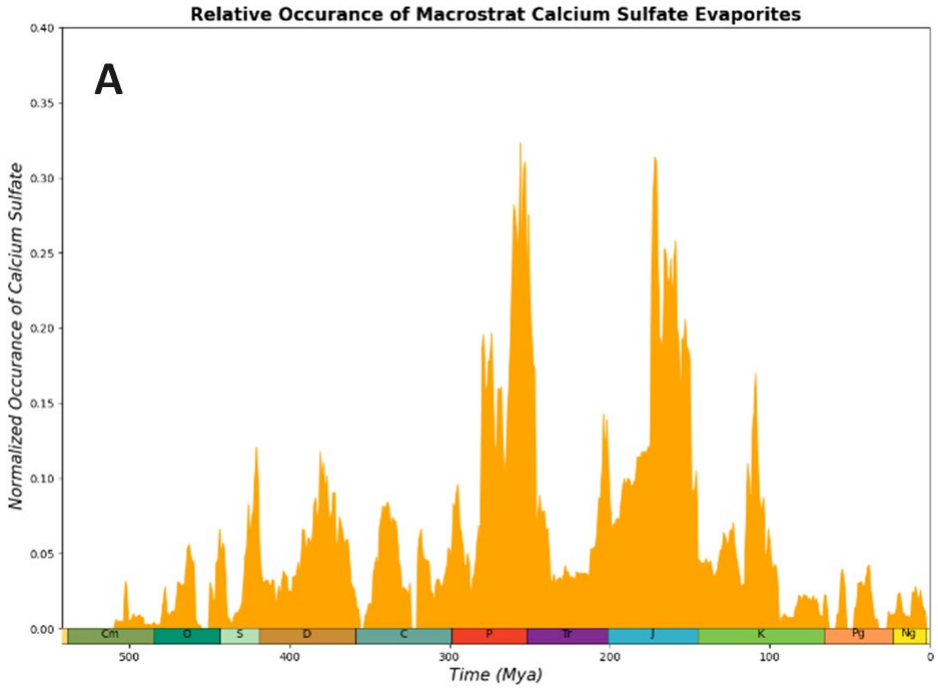
When binned in 1 Mya intervals there are various temporal changes seen in the relative sulfate record. For example, there are abrupt increases in the RAC at 350 million years and 250 million

years although these are less obvious when the data are binned in larger time intervals. When considering the full time series, the RAC increases steadily from the start of the Phanerozoic until approximately the Permian-Triassic boundary and then stays roughly constant, perhaps slightly decreasing, until present. The uncertainty in this record is greater for older deposits meaning the ratio of $CaSO_4$ evaporites is less well constrained during the Cambrian than in more recent Periods.

Macrostrat Evaporite Record

The Phanerozoic record of gypsum-bearing evaporites, anhydrite-bearing evaporites, halite-bearing evaporites, and marine carbonates within the North America set of the Macrostrat database was analyzed to compare the RAC from this dataset with the results from the GDD document set. As with the GDD data, gypsum-bearing evaporites and anhydrite-bearing evaporites were combined into $CaSO_4$-bearing evaporites. Additionally, data was compiled for marine carbonate mineral bearing units. There were 650, 65, and 12,562 unique deposits for $CaSO_4$, halite, and marine carbonate, respectively. The temporal occurrence of halite-bearing evaporites, $CaSO_4$-bearing evaporites, and marine carbonates are plotted in Figure 3.4. $CaSO_4$-bearing evaporites are found throughout the Phanerozoic with the highest number of occurrences being in the Permian as observed in the GDD dataset (Fig. 3.2). Halite-bearing evaporites are found sporadically through the Phanerozoic N. America database in Macrostrat, with many geologic periods having little to no halite evaporite occurrences. Marine carbonates are found in rocks of all ages through the Phanerozoic.





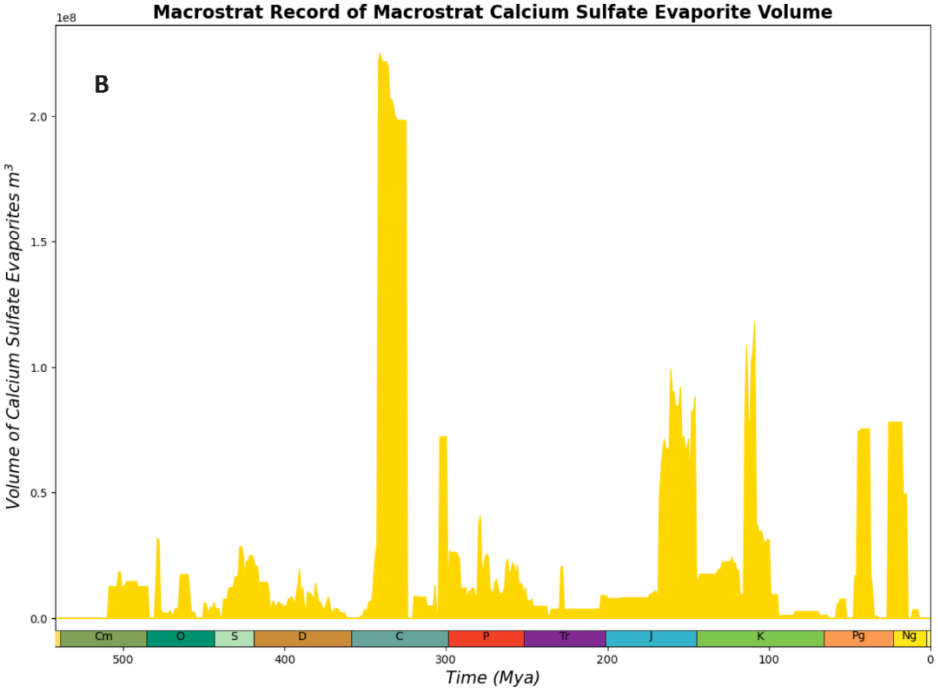


Figure 3.4: Plots showing temporal distribution of unique $CaSO_4$ occurrences throughout the Phanerozoic binned at 1-million-year time intervals from Macrostrat.

Far fewer occurrences of halite are present within the Macrostrat Database in comparison to the GDD document set, therefore the relative occurrence and proportion of $CaSO_4$ could not be analyzed in the same way. Instead, due to the prevalence of marine carbonate in Macrostrat, the volume of $CaSO_4$-bearing evaporites of any age was normalized to volume of marine carbonate. The "col_area", "prop", and "min_thick", "max_thick" data fields in Macrostrat were used to determine the volume of $CaSO_4$ bearing evaporites and marine carbonate at any given time with the results shown in Figure 3.5.

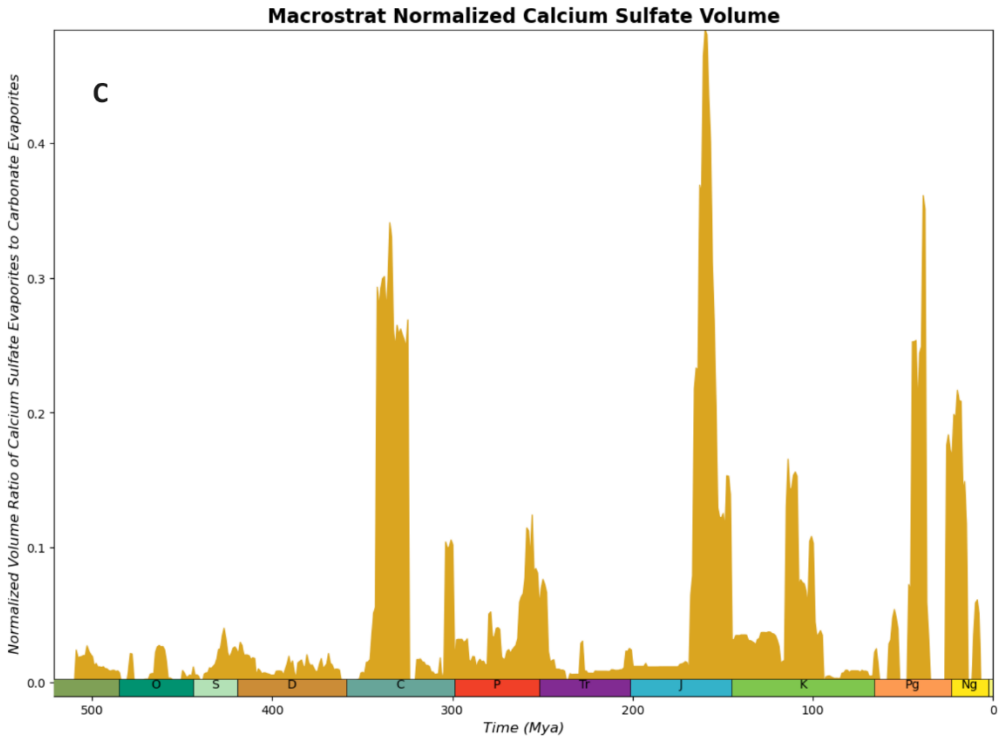

Figure 3.5: The abundance of North American Phanerozoic calcium sulfate evaporites obtained from Part A shows the relative number of occurrences of $CaSO_4$ in comparison to marine carbonate binned in 1-million-year intervals; B shows the volume $CaSO_4$ evaporites found in rocks of any given age; C shows the volume of $CaSO_4$ evaporites normalized to the volume of marine carbonate in 1-million-year intervals.

The results in Figure 3.5 show that the ratio of the number of $CaSO_4$-bearing evaporites to marine carbonates is highest during the Permian and Jurassic within the Macrostrat N. American database (Figure 3.5A). In contrast, the largest volumes of $CaSO_4$-bearing evaporites preserved in the geologic record are in the Carboniferous (Figure 3.5B). This could help provide context to understand the relative increase of calcium sulfate observed in Figure 3.3A occurring near the beginning of the Cretaceous. Peaks in the ratio of $CaSO_4$-bearing evaporites to marine carbonates are also observed in the Cretaceous and Jurassic (Figure 3.5C).

3.4 Occurrence of dolomite in the Macrostrat database

The Macrostrat database was also queried to provide the area of any column, with a lithology described as a carbonate, which contained dolomite. This was tabulated and recorded for all other carbonates separate from dolomite. To analyze the aerial extent of dolomite throughout the Phanerozoic the relative abundance of dolomite was calculated. This was achieved by normalizing the area of all dolomite bearing columns during a given time interval to the area of all carbonates bearing columns at the same time. A 1-million-year time bin was used and a time series of the Phanerozoic relative abundance of dolomite in comparison to all carbonates was generated (Figure 3.6).

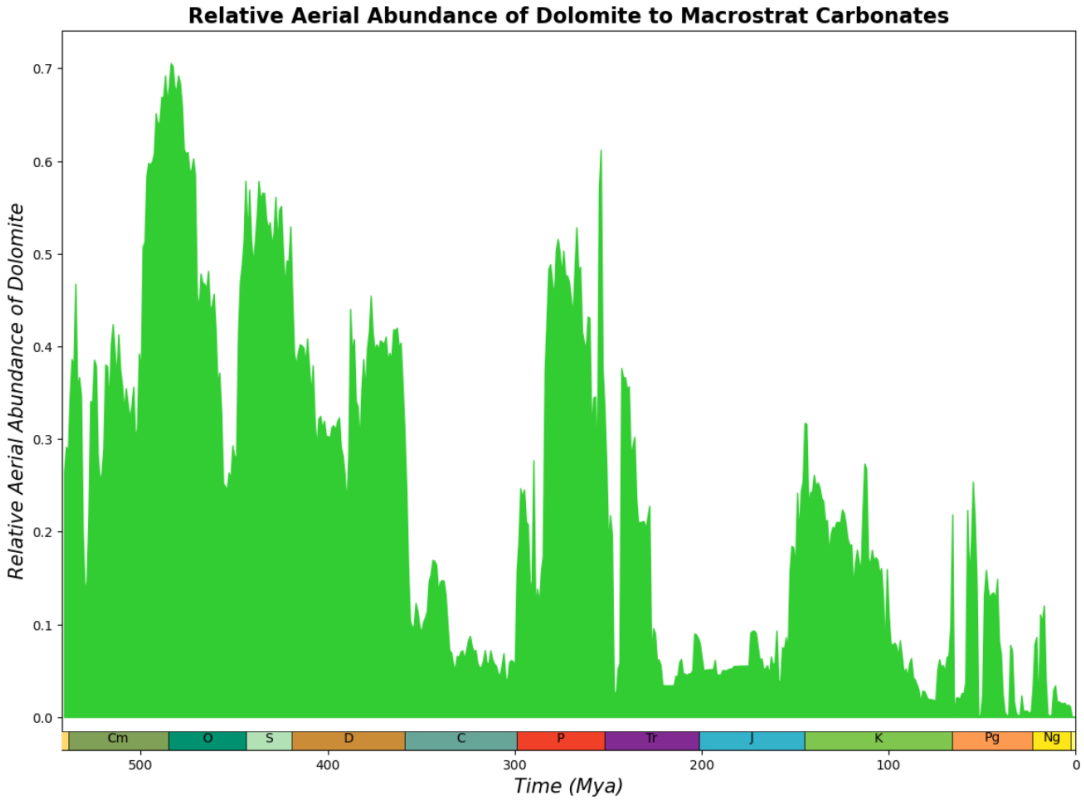

Figure 3.6: Plot showing the ratio of the area of all dolomite bearing columns within the Macrostrat database of a given age to the area of all carbonates of the same age using 1-million-year time increments.

In the Macrostrat database the ratio of dolomite to all marine carbonates is highest between 541-350 Mya and 289-240 Mya. The large decrease in the fraction of carbonates that are dolomite at approximately 350 million years ago occurs at the same time that the largest volume of $CaSO_4$ evaporites are preserved in N. America as obtained from the Macrostrat database (Figure 3.5B).

Chapter 4 PHREEQC Batch Evaporation Modeling

To explore a possible explanations an increase in the RAC from the Cambrian to the Cretaceous (Fig. 3.3), as well as rapid changes in RAC at various times in Earth history, a batch evaporation model was developed to better understand how changes in atmospheric or ocean chemistry can influence the amount of $CaSO_4$ that precipitates before halite saturation. A python code was written to do this based around the PHREEQC aqueous chemistry model (Parkhurst and Appelo, 2013).

4.1 Experiment design and model parameterization

To test the hypothesis that variation in the major ion composition of seawater over the Phanerozoic control's the relative amounts of $CaSO_4$ and halite found in evaporite deposits, I undertook several experiments using a geochemical model I developed based on a python implementation of PHREEQC (Parkhurst and Appelo, 2013). These are aimed at evaluating which changes in seawater chemistry can affect the abundance or presence of evaporite minerals. Specifically, this approach is an attempt to clarify if changes of seawater composition, within the ranges postulated by existing proxies, may have influenced the mineral occurrences observed within marine evaporites and affect the formation of halite vs $CaSO_4$ within an ideal marine evaporite forming basin. Batch evaporation experiments were performed by varying the initial concentrations of $[Ca^{2+}]$, $[SO_4^{2-}]$, Salinity, and pCO_2 to examine the influence of major chemical components of seawater and the subsequent evaporite formations they produce. An atmosphere of

CO_2 (g) held at $10^{-3.5}$ atmospheres (atm) was equilibrated with the solution at every reaction step except in the models where pCO_2 was varied.

To benchmark the results of the model, the model batch evaporation experiments conducted by Blättler et al. (2020), also based on the PHREEQC aqueous chemistry model, were replicated and analyzed by comparing the degree of evaporation at which gypsum becomes saturated, using 95 different initial fluid compositions (Figure 4.1A, Appendix 1). The comparison indicates my results match those from Blattler et al. (2020) with good accuracy. In comparing the results (Figure 4.1B), the values obtained from my experiment were on average 0.5 units greater than Blättler et al. (2020), over degree of evaporation values that range from 0.1 to 55. Such small differences probably reflect difference in the step size in the evaporation process and numerical rounding. These tests were performed using the input files provided in the appendix of Blattler et al. (2020), and the exact same input parameters listed within their supplementary data.

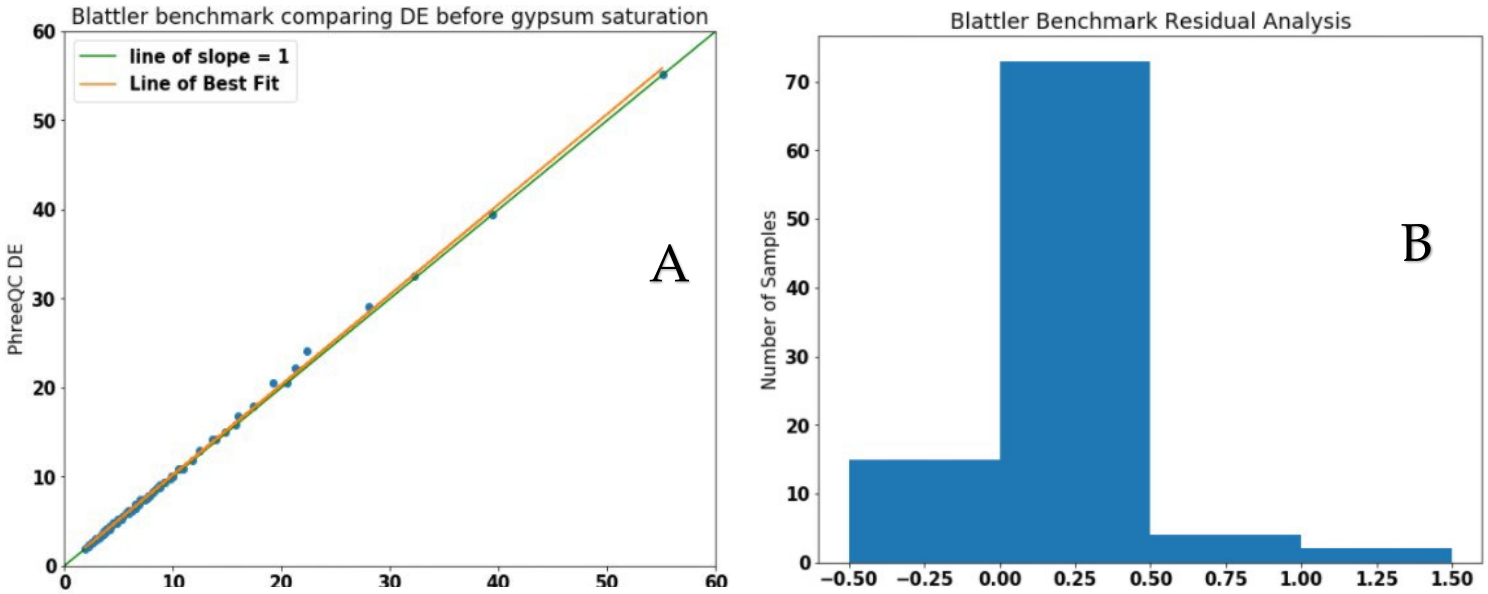

Figure 4.1: Model validation using published PHREEQC results from Blättler et al. (2020). (A) My results for degree of evaporation at gypsum saturation are plotted on y-axis and the x-axis shows the results from Blättler et al. (2020). Line of best fit in orange, and the one-to-one line is in green. (B) Histogram showing the residual differences defined as between my results minus the results from Blättler et al. (2020). Most of my results are less than 0.5 units greater.

Several batch evaporation experiments were conducted within PHREEQC V. 3.9 by implementing a similar method to Blättler et. al. (2020). My experiments invoked an idealized scenario for evaporite formation that neglects freshwater input and any external mixing components, such as recharge. I also restricted the phases allowed to precipitate within the model to prevent glauberite from crystallizing. The Pitzer database was used to calculate ion activity coefficients in the model solutions due to their high ionic strength. Models were performed starting with a solution mass of 1 kg, temperature was fixed at 25°C, and a constant redox state of 8.413 mV. The solution was evaporated by removing water in progressively decreasing quantities of 1, 0.5, 0.2 0.1, or 0.05 moles of water per evaporation step, with the step size depended on the moles of water remaining (Table 4.1).

The amount of evaporation per reaction step in PHREEQC				
SM > 10.1 M	10.05 M>SM>7.55 M	7.55 M>SM>1.55 M	1.55 M>SM>0.45 M	0.45 M > SM
1 mol	0.5 mol	0.2 mol	0.1 mol	0.05 mol

Table 4.1: The amount of evaporation per timestep, where SM is the number of moles of H_2O remaining in the evaporating solution (initial = 55.55 moles in one kilogram at standard temperature and pressure). The decrease in evaporation per time step in the models with decreasing mass of water remaining ensures the timing of saturation of each phase is precisely constrained. The simulations stop after 55.15 moles of water have evaporated.

The following phases were allowed to precipitate: Anhydrite, Arcanite, Bischofite, Bloedite, CO_2, Calcite, Carnallite, Celestite, Epsomite, Glaserite, Glauberite, Gypsum, Halite, Hexahydrite,

Kainite, Kieserite, Leonhardite, Leonoite, $MgCl_2$, Mirabilite, Pentahydrite, Polyhalite, Schoenite, Sylvite, Syngenite, and Thenardite (Table 4.2). The concentrations of the following species were specified in the initial system modelled: Ca^{2+}, Mg^{2+}, Sr^{2+}, Na^{+}, K^{+}, Cl^{-}, SO_4^{2-}, and CO_2 (g).

Precipitating Phases	
Anhydrite	$CaSO_4$
Arcanite	K_2SO_4
Bischofite	$MgCl_2 \cdot 6H_2O$
Bleodite	$Na_2Mg(SO_4)_2 \cdot 4H_2O$
Carbon Dioxide	CO_2
Calcite	$CaCO_3$
Celestite	$SrSO_4$
Epsomite	$MgSO_4 \cdot 7H_2O$
Glaserite	$(K,Na)_3Na(SO_4)_2$
Glauberite	$Na_2Ca(SO_4)_2$
Gypsum	$CaSO_4 \cdot H_2O$
Halite	NaCl
Hexahydrite	$MgSO_4 \cdot 6H_2O$
Kainite	$KMg(SO_4)Cl \cdot 3H_2O$
Kieserite	$MgSO_4 \cdot H_2O$
Leonhardite	$CaAl_2Si_4O_{12} \cdot 3H_2O$
Leonite	$K_2Mg(SO_4)_2 \cdot 4H_2O$
Magnesium Chloride	$MgCl_2$
Mirabilite	$Na_2SO_4 \cdot 10H_2O$
Pentahydrite	$MgSO_4 \cdot 5H_2O$
Polyhalite	$K_2Ca_2Mg(SO_4)_4 \cdot 2H_2O$
Schoenite	$K_2Mg(SO_4)_2 \cdot 6H_2O$
Sylvite	KCl
Syngenite	$K_2Ca(SO_4)_2 \cdot H_2O$
Thenardite	Na_2SO_4

Table 4.2: Minerals allowed to precipitate in PHREEQC with their mineral formulas. Glauberite was withheld as a phase while varying [SO_4^{2-}], as described in the text.

Batch evaporation calculations were stopped when 55.15 moles out of one liter of water has been removed via evaporation. Alkalinity was held constant across all initial solution concentrations at 2.4 m_{eq}/kg accounting for the charge imbalance of the major ions in seawater.

The mass of evaporite phases formed during evaporation, and the degree of evaporation required for phase saturation, were tabulated and analyzed across all batch evaporation experiments. The degree of evaporation (DE) required for phase saturation is the DE when the phase first becomes saturated; for example, the DE required for phase saturation for calcite is 0 because the solution is initially saturated with respect to calcium carbonate. For the experiments pertinent to the questions of this study, the degree of evaporation is defined as the percentage of the initial mass of water that has been removed from solution at any given stage, where *DE(x)* is the degree of evaporation of the solution ranging from 0 to 99.98 and is inversely proportional to the solutions mass. M_i denotes the initial mass of solution, which is 1 kg of water in all simulations, *S(x)* denotes the mass of water at reaction step *x* (Eq. 4.1).

$$DE(x) = \frac{(M_i - M)}{M_i} \times 100 \qquad \textbf{Eq. 4.1}$$

The mass of each phase formed throughout the model, degree of evaporation at which a precipitated phase begins to form, and the internal PHREEQC solution parameters were tabulated in the model results. All results were obtained from parsing PHREEQC output files.

Numerical experiments were performed to test how changes in seawater [Ca^{2+}], [SO_4^{2-}] and salinity, as well as atmospheric pCO_2, could change the RAC. While intuition could be used to make predictions, such as that higher Ca^{2+}would lead to earlier gypsum saturation all other things being equal, the complexity of the system makes such an approach questionable. For example, if increases in the concentration of one species leads to saturation of a different phase the result may be non-intuitive. Further, changes in activity coefficients can complicate the results.

4.2: PHREEQC Experimental

4.2.1. Varying the product of [Ca^{2+}] and [SO_4^{2-}]

The concentration of Ca^{2+} and SO_4^{2-} in seawater have a direct control on the formation of gypsum, and it is widely believed that the concentration of these species in seawater changed over the Phanerozoic (e.g., Horita et al., 2002; Lowenstein et al., 2003). To test whether changes in the concentrations of [Ca^{2+}] and [SO_4^{2-}] in seawater could have controlled the changes in the relative proportions of gypsum and halite observed in evaporites (Fig 3.3), experiments were performed using PHREEQC in which the concentration of these species were varied independently of one another. Charge balance was maintained for experiments using variable Ca^{2+}concentrations via increasing [Cl^-] and [Ca^{2+}] and decreasing [Na^+] in 1 mmol/kg increments from their initial value in the PHREEQC model. In the first experiment, [Ca^{2+}] in the starting solution was varied between 4 and 33 mmol/kg while holding SO_4^{2-} constant at 20 mmol/kg. In a second experiment the [SO_4^{2-}] concentration in the solution was varied at constant [Ca^{2+}]. The charge balance of solution when [SO_4^{2-}] was varied was maintained by increasing concentrations of [Na^+] and [SO_4^{2-}] and decreasing [Cl^-] in 1 mmol increments from their initial value. The batch evaporation experiment with variable concentrations of SO_4^{2-} used initial solution concentrations ranging from 4 mmol/kg to 33 mmol/kg in 1 mmol increments, with Ca^{2+} held constant a 10.3 mmol/kg. Parameter space explored by these models was set in order to see if there were any changes in the relationship between the degree of evaporation required to form the phase and the initial solution concentrations of [Ca^{2+}] and [SO_4^{2-}] for their respective experiments.

Changes in the degree of evaporation required for phase saturation, and in the quantity of the phase formed were recorded for different starting solution compositions. Glauberite

($Na_2Ca(SO_4)_2$) was artificially prevented from precipitating in the PHREEQC code (i.e., suppressed) because otherwise changes in solution Na^+ content, used to maintain charge balance in the starting solutions, would drive glauberite saturation and draw Ca^{2+} and SO_4^{2-} out of the solution. Due to glauberite's relatively low abundance in natural systems, in comparison to $CaSO_4$ and halite, its omission should not impact the model results significantly.

4.2.1.1. Results from varying the concentration of [Ca^{2+}]

PHREEQC simulation results show that as the concentration of Ca^{2+} in the starting solution increases, at constant [SO_4^{2-}], the precipitation of gypsum occurs earlier in the evaporation process (Figure 4.2). The degree of evaporation required for gypsum saturation decreases approximately 38% as the starting solution Ca^{2+} concentration increases from 4 to 33 mol/kg. The change in Ca^{2+} concentration had negligible effect on the degree of evaporation required for halite saturation even though charge balance was maintained by manipulating the concentration of Na^+ and Cl. All other things being equal, this suggests that the Ca^{2+} concentration in seawater may have played an important role in controlling the relative abundance of gypsum in Phanerozoic evaporites; i.e., higher Ca^{2+} concentrations would lead to gypsum precipitation at a lower degree of evaporation, but with no change in the degree of evaporation required for halite saturation, and hence there would be a higher probability of forming an evaporite deposit containing gypsum but not halite.

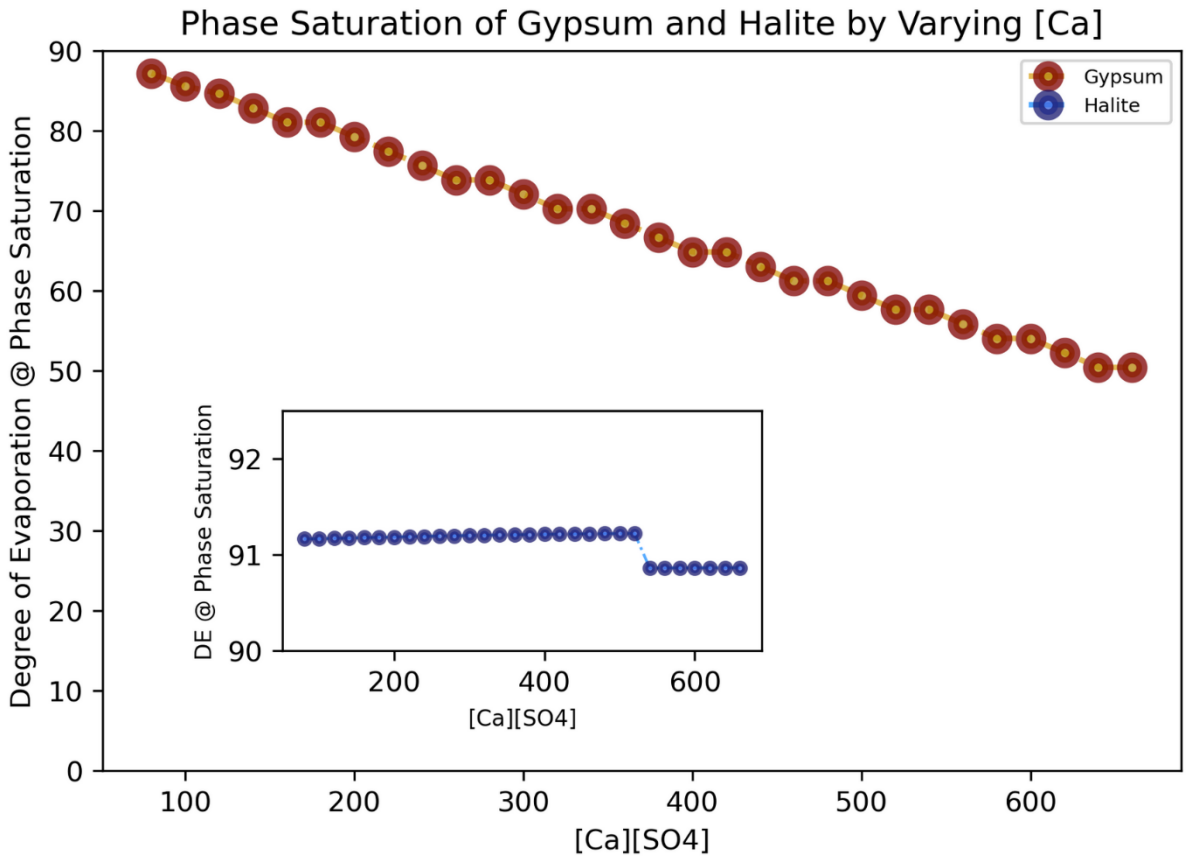

Figure 4.2: The product of [Ca^{2+}] and [SO_4^{2-}] in the starting solution, which varies solely through changing [Ca^{2+}], plotted against the degree of evaporation at which gypsum begins to form. The inset shows the degree of evaporation at which halite forms within this experiment plotted against the same x-axis limits as in the larger plot (note the expanded scale).

4.2.1.2. Results from varying the concentration of [SO_4^{2-}]

A PHREEQC simulation was run to analyze changes in the precipitation of gypsum or halite when the concentration of sulfate in seawater was varied with [Ca^{2+}] held constant. This simulation allowed me to investigate how different levels of sulfate in seawater affect the degree of evaporation required for the formation of gypsum and halite, and hence their relative abundance in evaporite deposits.

The results of the PHREEQC simulation showed that the degree of evaporation at

gypsum saturation decreased with increasing [SO_4^{2-}] as was observed in the models varying [Ca^{2+}]. Model results show that the degree of evaporation required to precipitate gypsum from solution is approximately the same for [SO_4^{2-}] as it was for [Ca^{2+}], decreasing the degree of evaporation at phase formation by 37% as [SO_4^{2-}] increased from 4 to 33 mol/kg with [Ca^{2+}] held constant and, again, with no change in the degree of evaporation required for halite saturation (Figure 4.3). Thus, increases in concentrations of Ca^{2+} or SO_4^{2-} can significantly impact the relative timing of $CaSO_4$ versus halite saturation, and are potential explanations for the changes in RAC documented in Chapter 3.

4.2.3 Varying Salinity

The salinity of seawater has been hypothesized to have changed over the Phanerozoic

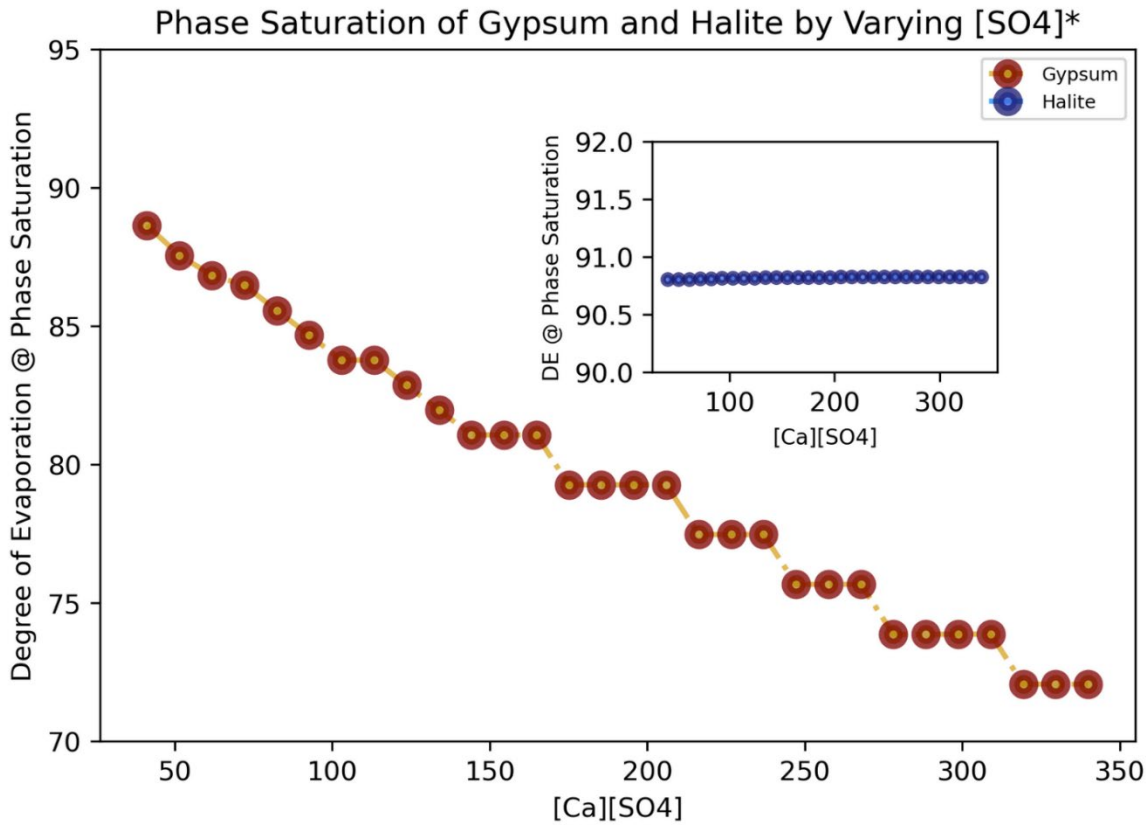

Figure 4.3: The product of [Ca^{2+}] and [SO_4^{2-}] in the starting solution plotted against the degree of evaporation at which gypsum begins to form from solution while [SO_4^{2-}] is varied at constant Ca^{2+} (10.3 mmol kg^{-1}). The inset shows the of the degree of evaporation at which halite forms within this experiment plotted on the same axes (note the expanded y-scale).

(e.g., Hay et al., 2006). Estimates of the salinity of seawater during the Phanerozoic range from ~34‰ to ~57 ‰ (e.g., Hay et al., 2006). To test whether the salinity of seawater has a significant impact on the degree of evaporation at which halite begins to form, the concentrations of Cl^- and Na^+ were varied in the initial solution. For this batch evaporation experiment, all ions except Na^+ and Cl^- were held constant at modern values, while Na^+ and Cl^- were varied from modern values to 57 ‰ salinity to explore the parameter space suggested by Hay et al. (2006). Charge balance was maintained by increasing the concentration of Cl^- in equal molar amounts to that of Na. All the phases listed in Table 4.2 were allowed to precipitate in these experiments.

Results of the PHREEQC simulation showed that halite saturation occurred earlier in the evaporation process (lower DE) as the salinity of the starting solution increased. However, the results show only a 6.2% decrease in DE while the concentrations of [Na^+] and [Cl^-] were increased by 33% from the lowest salinity starting solution to the highest salinity starting solution (Figure 4.4). The results of this simulation demonstrate that the degree of evaporation required for halite precipitation is only weakly sensitive to the [Na^+] and [Cl^-] concentrations in the starting solution across the range of seawater compositions thought to have existed in the Phanerozoic. Based on this, it seems unlikely that the changes in relative abundance of $CaSO_4$ and halite deposits over the Phanerozoic (Fig. 3.3) are controlled by changes in seawater salinity.

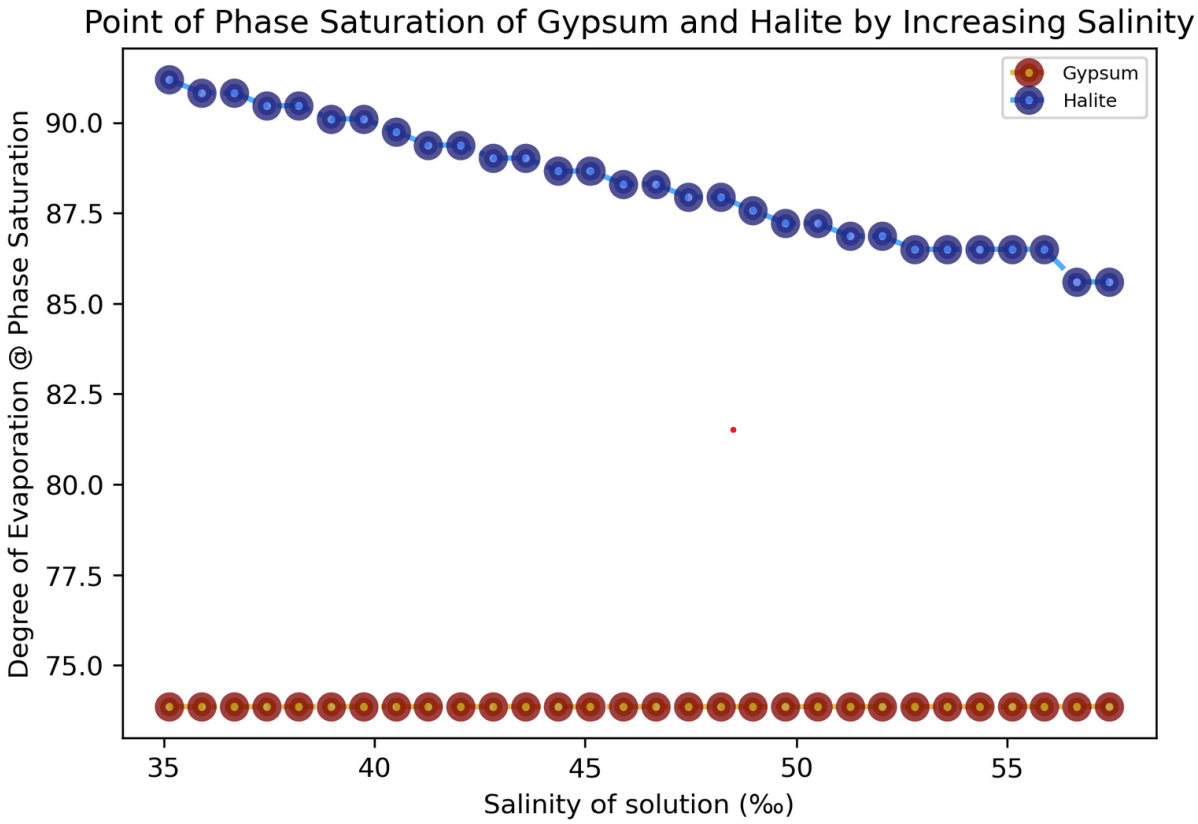

Figure 4.4: The degree of evaporation at which halite and gypsum form are shown against salinity of the starting solution. The degree of evaporation for gypsum formation does not change significantly in comparison to the degree of saturation required to form halite at a given salinity. It should be noted salinity is increased by approximately 25% however the degree of evaporation required to form halite only decreases by roughly 6%.

4.2.4. Varying pCO_2

Carbon dioxide is hypothesized to have varied dramatically over the Phanerozoic (Fig. 4.5; Berner and Kothavala, 2001). Dissolved carbon provides the ions to form marine carbonate minerals; however, the carbonate system is more complex and formation of carbonate minerals depends on several factors including alkalinity and also the concentration of CO_3^{2-} not simply DIC (total dissolved inorganic carbon). The speciation of DIC is a function of pH. Systems with

low solution pH have a smaller fraction of their DIC as the carbonate ion than systems with high pH. Changes in the saturation state of calcium carbonate minerals may play an important role in controlling the degree of evaporation at $CaSO_4$ mineral saturation through changing the concentration (and activity) of Ca^{2+} in the solution. Therefore, in an attempt to quantify the effect of atmospheric CO_2, another PHREEQC experiment was performed to analyze if pCO_2 has a significant effect on the degree of evaporation required to drive gypsum and halite saturation in seawater. Exact concentrations of the partial pressure of CO_2 across Earth history are poorly constrained; however, proxy data and modeling (e.g., Berner and Kothavala, 2001) suggest substantial variations in atmospheric CO_2 over the Phanerozoic. The values of pCO_2 used in the batch evaporation experiments explore the parameter space postulated by (e.g., Berner and Kothavala, 2001) which is a range from $10^{-3.5}$ to $10^{-2.15}$ atm (Figure 4.5).

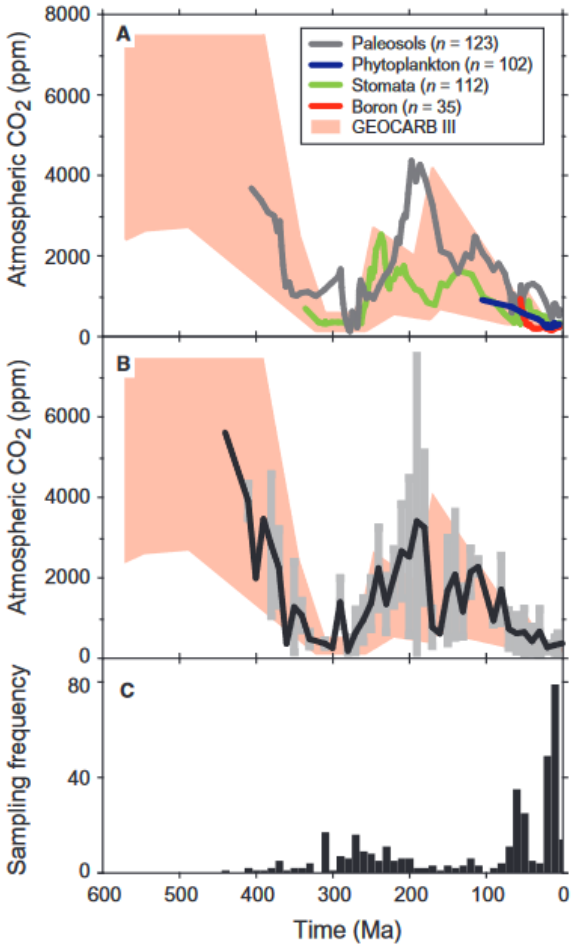

Figure 4.5: Figure showing: (a) various observational estimates of paleo-pCO_2, (b) a "best-estimate" (black line) and uncertainties (grey bars) and (c) number of data used to produce these estimates (from Royer et al., 2004). Parts (a) and (b) both show model estimates from GEOCARB III in orange.

PHREEQC ion concentrations were varied between two different scenarios, one using the composition of modern seawater (Table 4.2) and the other using an ionic composition similar to a Cretaceous seawater (Table 4.2).

Simulation Name	Temp (°C)	Alk	Ca	Cl	K	Mg	Na	SO_4	Sr	Log[pCO_2]
pCO_2 {Ca > SO_4} $_{init}$	25	2.4	35	603.18	12	49	445	11	0.09	-2.15

Table 4.3: Compositions of initial solutions shown as the range of the variables changed for each experiment. The range of batch reaction experiments are shown as *init* and *final* within the simulation name column. Concentrations of ions are in milli-molar (mM) and pCO_2 is in (atm). Charge balance for batch reaction experiments varying Ca^{2+} or SO_4^{2-} by changing concentrations of Na^+ and/or Cl.

Models of evaporation of these two seawater compositions, with different atmospheric pCO_2 concentrations, were used to examine if changes in pCO_2 and dissolved carbon changes the relative timing of gypsum and halite saturation and whether any effect is greater when calcium concentrations are higher than the concentration of sulfate and vice versa. Charge balance of the initial solution was maintained across the range of inputs in this experiment by holding the concentrations of major ions constant. All phases specified in Table 4.2 were allowed to

precipitate.

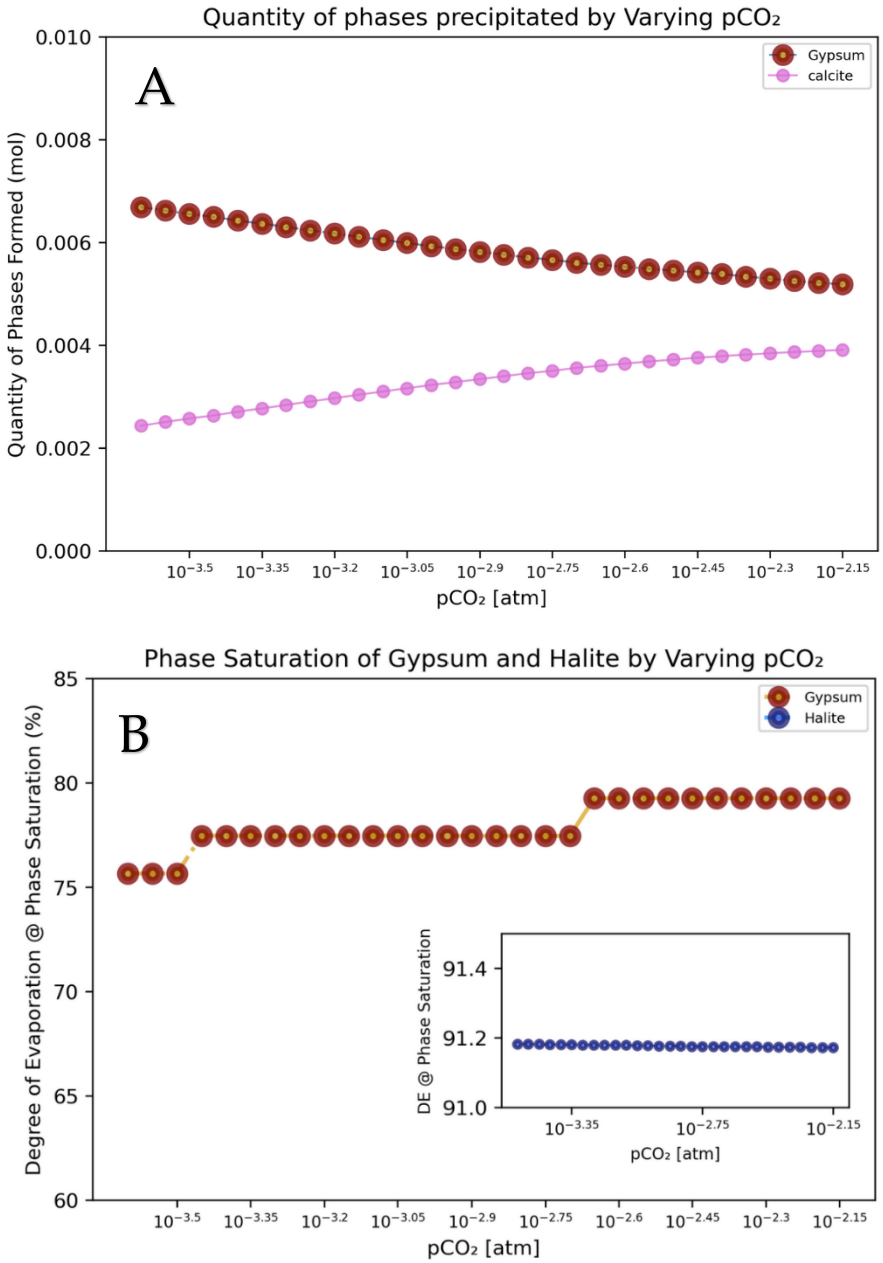

Figure 4.6: (A) The amount of gypsum formed from batch reaction experiments where $[SO_4^{2-}] > [Ca^{2+}]$ in the initial solution (i.e., using modern seawater composition; Table 4.2). As pCO_2 increases there is less gypsum formed (22.4% decrease). Increasing pCO_2 within ranges possible in the Phanerozoic caused the total amount of gypsum to precipitate to be approximately 20% less than when pCO_2 was lower. **(B)** The degree of evaporation at the onset of gypsum precipitation from the same batch evaporation experiment shown in**.** The inset plots shows the same things but for halite. As pCO_2 increases gypsum precipitation occurs later in the experiment relative to experiments with lower pCO_2 values

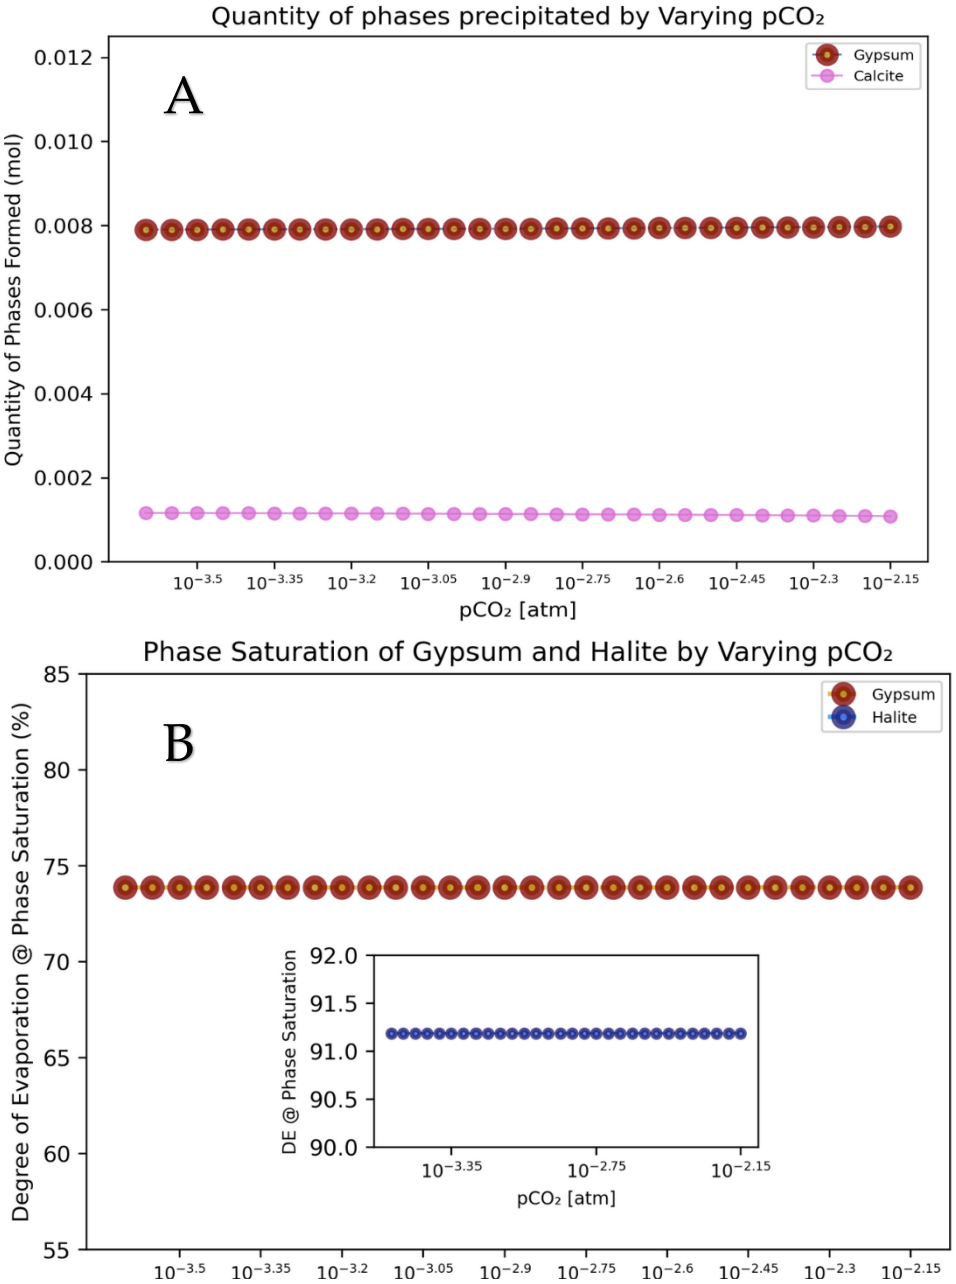

Figure 4.7: (A) The amount of gypsum formed from batch reaction experiments where $[SO_4^{2-}] < [Ca^{2+}]$ in the initial solution (Table 4.2). As pCO_2 increases there is no increase in the amount of carbonate or gypsum formed throughout the experiments. (B) The degree of evaporation at the onset of gypsum precipitation from the batch evaporation experiment shown in part, the inset plot shows the degree of evaporation at halite saturation doesn't change across these experiments. As pCO_2 increases there is no effect on gypsum saturation from varying pCO_2 when calcium concentrations are greater than sulfate.

As shown in Figures 4.6 and 4.7, the effect of varying pCO_2 has a different influence on the degree of evaporation at calcium sulfate saturation, and the amount of calcium sulfate formed, in the experiments where $[SO_4^{2-}] < [Ca^{2+}]$ and $[SO_4^{2-}] > [Ca^{2+}]$ which broadly represent Cretaceous and modern seawater chemistry. When $[SO_4^{2-}] < [Ca^{2+}]$ there is no significant effect of the quantity of carbonate or calcium sulfate minerals precipitated from solution as pCO_2 is changed in the models. Additionally, there is no effect of the onset of saturation of calcium sulfate. Calcium sulfate saturation is not affected because calcium sulfate formation is limited by $[SO_4^{2-}]$ since $[Ca^{2+}]$ is the more abundant ion. In contrast, when $[SO_4^{2-}] > [Ca^{2+}]$ in the initial solution of the batch evaporation experiments, varying $pCO_{2\ does}$ change the degree of evaporation required for saturation of calcium sulfate and also affects the amount of calcium sulfate formed (Figure 4.6A and 4.6B). When using pCO_2 concentrations within the range thought to have existed in the Phanerozoic, the amount of calcium sulfate formed during the times with the highest pCO_2 concentrations is 22.4% lower than when the pCO_2 in the model is at the lowest end of the range believe to have existed in the Phanerozoic (Fig. 4.6). In addition, the onset of calcium sulfate saturation increases as pCO_2 increases by ~5%. These changes reflect changes in the amount of Ca^{2+}removed from the starting solution into carbonate minerals, leaving less $Ca^{2+}$to form $CaSO_4$. The decrease in calcium sulfate formed and the change in the degree of evaporation required for $CaSO_4$ saturation shown in Figure 4.6A and 4.6B, could provide at least part of the explanation of the changes in the relative abundance of carbonate shown in Figure 3.3.

Chapter 5 Discussion

5.1 Relative Abundance of $MgSO_4$ and KCl Evaporites

The abundance of KCl and $MgSO_4$ bearing evaporite deposits observed in the record collected from the GDD document set (Figure 3.1) provides a more complete set of evaporite occurrences from the Phanerozoic than that has hitherto fore been available and provides additional insight into the temporal abundance of these two evaporite minerals. Utilizing this size of a dataset allows a larger set of data to evaluate the temporal abundance of these two evaporite minerals. Within the GDD result set, there is a near continuous occurrence of KCl found in marine evaporite deposits throughout the Phanerozoic (Figure 3.1B). Marine KCl bearing evaporite deposits were found throughout the Phanerozoic overlapping during intervals where $MgSO_4$ bearing evaporite deposits were also present, contrary to the data presented in Hardie (1996). $MgSO_4$ evaporites were far less abundant in the document set. $MgSO_4$ deposits were found in the GDD document set during the late Devonian through the early Triassic and in evaporites formed since the Paleogene. This record provides 41 more KCl units and 21 fewer $MgSO_4$ observations than a comparable dataset compiled by Hardie (1996) and Zharkov, (1974). Despite slightly more units when considering both KCl and $MgSO_4$, these results show a more complex picture of secular occurrence of marine evaporites than previously described in the literature.

The occurrence of KCl-bearing and $MgSO_4$-bearing minerals in distinct evaporite units is the greatest during the Carboniferous to early Triassic time intervals (Figure 3.1). This is consistent with the dataset derived from Hardie (1996) and a review of the evaporite deposits described in Zharkov (1974), however KCl evaporites described in Zharkov (1974) which overlap temporally with marine $MgSO_4$ evaporites were described as forming from carnallite ($KCl.MgCl_2 \cdot 6H_2O$) dissolution and recrystallization into sylvite and not primary occurrences of sylvite (KCl). This

nuance was not provided in entries where KCl evaporites were found from the GDD dataset. Stratigraphic units described as containing marine evaporites are evaluated on a basis if that lithology has a marine origin. Post-diagenetic alteration can occur within a marine evaporite formation distorting the sequence of potash and late-stage evaporite minerals preserved the extent of textures and features required to segregate primary and secondary marine evaporites was not taken into account within the text-mining model, therefore the GDD results from my text-mining program cannot account for these instances. Sylvite occurrences were more abundant in my GDD text-mining results than in the datasets of Hardie and Zharkov. Because most sylvite found in evaporites co-occur with epsomite and could have formed from dissolution of other potassium bearing phases, the primary vs. secondary nature of sylvite units in the GDD data set cannot be determined, but it still provides a high-level record of K-bearing evaporite mineral abundances across the Phanerozoic.

In the dataset provided by GDD, $MgSO_4$ evaporites were found outside the boundaries published in the Hardie (1996) dataset. $MgSO_4$ bearing evaporites were found as early as the middle Devonian and as late as the early Triassic. The number of $MgSO_4$ occurrences within the document set were far fewer than identified by Hardie (1996), however that could be a result of the document set analyzed. If the GDD library did not contain many papers that contained descriptions of $MgSO_4$ as a marine evaporite using in-text descriptions (which are easiest for the text mining program to extract). However, the presence of MgSO4 units older than those documented in Hardie (1996) is broadly consistent with observations in fluid-inclusion analyses, which have recorded an elevated $Mg_{[mol]}/Ca_{[mol]}$ as early as the Mid-Devonian (Figure 1.3). The analysis of these results shows that text-mining a diverse document set using simple logical rules to evaluate information from scientific publications can provide additional insight that is also

observed using modern quantitative methods. As a qualitative analysis of the occurrence of specific evaporite phases, new information can be obtained, and older hypotheses can be evaluated by analyzing the existing literature of a particular field.

The abundance of KCl-bearing evaporites found throughout the Phanerozoic shows that potassium bearing phases were able to precipitate in various evaporite deposits during discrete intervals where it was suggested they should not form. Basins on continental margins are subject to dissolution and influence from continental and rainwater. However, it has been argued that potassium has been nearly constant throughout the Phanerozoic at approximately 10.3 mMol/L and the results from this analysis suggest potassium could not have varied significantly across the Phanerozoic. The large increase of KCl bearing evaporites found in the Permian seem to be due to a preservation bias observed in halite and calcium sulfate bearing evaporite deposits (Figure 3.2). However, this analysis cannot rule out a potential large sink for potassium that would change based upon sea level change. Recent studies are now questioning the long-held assumption that potassium has remained constant throughout the Phanerozoic (Nambiar et al., 2023).

5.2 Relative Abundance of Calcium Sulfate

Using the abundance of halite and calcium sulfate (anhydrite or gypsum) in the document set I have investigated using the relative abundance of calcium sulfate (RAC) can provide a new observation useful for reconstructing paleo-seawater composition. The lowest Phanerozoic values of the normalized ratio of calcium sulfate evaporite occurrences are found 400 million years ago (the Middle to Late Devonian) and older, within the data plotted in 1-million-year bins or bins grouped by International Epochs (Figure 3.3). In addition, prior the Middle to Late Devonian this record is highly variable on a shorter timescale then when compared to more recent periods of

Earth history. This high variability in the RAC could be explained by several geologic phenomena documented in the early Phanerozoic such as tectonic factors, a primitive sulfur cycle, the oceanic redox conditions, variable atmospheric conditions, or a preservation bias.

While poorly constrained, it has been suggested that early in the Phanerozoic the deep oceans had lower dissolved oxygen content than in the second half of the Phanerozoic potentially meaning larger portions of the oceans were anoxic (Stolper and Bucholz, 2019), and did not contain sufficient sulfate to form calcium sulfate that would be preserved as suggested by the RAC before 400 Mya. These are the oldest preserved evaporites in the Phanerozoic record and thus are likely to have eroded away, however, the increased occurrence of halite relative to calcium sulfate suggests that some other mechanism to cause decreased calcium sulfate evaporites is likely the driver. When evaluating the modeling experiments to change the degree of evaporation at gypsum precipitation, changing salinity was evaluated with respect to halite and gypsum formation to explore how changing ocean salinity could impact on the RAC record. When considering a 25% increase in salinity, the degree of saturation for halite formation only decreased by approximately 6%, suggesting even if salinity was at the highest level calculated by Hay et al., (2006), it would only marginally change the degree of saturation of halite and would still be much greater than gypsum.

Modeling results from PHREEQC batch evaporation experiments show that the mechanisms that effect the degree of evaporation at which gypsum is saturated are most influenced by changing pCO_2 where Ca^{2+} is the phase limiting ion ($SO_4^{2-} > Ca^{2+}$) or changing the concentration of Ca^{2+} or SO_4^{2-} (Figure 4.6). When evaluating the other modeling experiments to change the degree of evaporation at gypsum precipitation, salinity and pCO_2 ($SO_4^{2-} < Ca^{2+}$), there was minimal change observed in the batch evaporation experiments suggesting these two scenarios would not impact

the RAC record. Incorporating the record of fluid inclusion analysis from this time interval coupled with PHREEQC batch evaporation experiments, it is likely that Ca^{2+} was more abundant in brine forming solutions, therefore it is likely that varying pCO_2 did not attribute to the decrease or variability of the RAC and was more likely due to lower SO_4^{2-} concentrations in paleo-seawater preceding 400 Mya.

The RAC record after approximately 400 Mya shows variations around a long-term mean, when plotted in 1 Myr time bins (Figure 3.3). When the data is plotted using the 20^{th} and 80^{th} quartiles, there is a cyclic pattern emerging from the RAC ranging from approximately 0.8 to 0.5 where calcium sulfate occurrences as or more common than halite occurrences (Figure 3.3A). This could be explained by changes in Ca^{2+} and SO_4^{2-} concentrations that led to cycles in the saturation state of $CaSO_4$ in seawater within this time frame. When data are binned into International Epochs, the oscillatory behavior of the record is no longer observed, and the variability of the RAC is constrained between 0.65 and 0.57 (Figure 3.3B).

One of the major assumptions regarding paleo-seawater composition is that the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ has ranged between 150 – 450 $mmol^2$, or a value of 300 $mmol^2$ similar to modern seawater concentrations. Which value(s) to use is unconstrained, however the value of the product of Ca^{2+} or SO_4^{2-}, whichever ion which has been completely removed from solution prior to halite precipitation and hence is not measured in fluid inclusion studies (Holland, 1972; Horitia et al., 2002; Lowenstein et al., 2005). For example, when $[Ca^{2+}] > [SO_4^{2-}]$, the concentration of sulfate must be calculated through this assumption, and vice versa. The RAC may provide a constraint on this assumption as follows. When the RAC is higher than the modern value (~0.7), the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ is likely to have been greater than 300 $mmol^2$ and when the RAC is less than the modern value the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ in seawater is likely to have been less than 300

$mmol^2$. While this approach ignores differences in preservation potential of halite and gypsum in the geological record, it provides the first quantitative approach to improving on the assumption used in previous studies that the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ in seawater has remained constant throughout the Phanerozoic.

Using the RAC record to quantitatively constrain the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ in seawater is not possible currently, but qualitatively it can be used to determine whether this product was higher or lower than the modern. In effect this means instead of having error bars on estimates of $[Ca^{2+}]$ and $[SO_4^{2-}]$ concentrations, we have limits on these instead. To show how the RAC record could be qualitatively used in this way, the fluid inclusion derived record of $[Ca^{2+}]$ and $[SO_4^{2-}]$ (Lowenstein et al., 2003) has been annotated with black arrows (Figure 5.1).

If the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ is leading to a higher value observed in the RAC the assumed concentration of the ion measured in fluid inclusion analysis might be greater or lower than previously considered. For example, if the RAC tends to a higher value it is possible that the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ are higher, and therefore the assumed ion concentration could be greater as indicated with the black arrow pointing up, and visa versa for values that are near minimums observed in the RAC. As stated previously, the assumption that the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ were constant throughout the Phanerozoic is not quantitatively constrained and could have varied more than the range originally postulated. Within PHREEQC experiments the greatest product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ considered was 635 $mmol^2$, while the minimum considered was 41.2 $mmol^2$ and did not change the order of evaporite mineral formation to change significantly beyond what has been observed throughout the Phanerozoic record. This evidence suggests that the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ could have been above or below the bounds used in the calculation of fluid inclusion data and that paleo-seawater concentrations could be more concentrated or more

dilute with respect to [Ca^{2+}] and [SO_4^{2-}] while yielding evaporite deposits consistent with the Usiglio sequence observed throughout the Phanerozoic. Using RAC as a general inference as to the behavior of [Ca^{2+}] and [SO_4^{2-}] a qualitative record improves the understanding of seawater chemistry through Earth history, highlighting where a change in the [Ca^{2+}] and [SO_4^{2-}] could have been significant. By using this record and building upon the text-mining extractions, allowing for more data to be collected or future attempts will provide a more constraints on reasonable ranges of product of [Ca^{2+}] and [SO_4^{2-}] throughout the Phanerozoic.

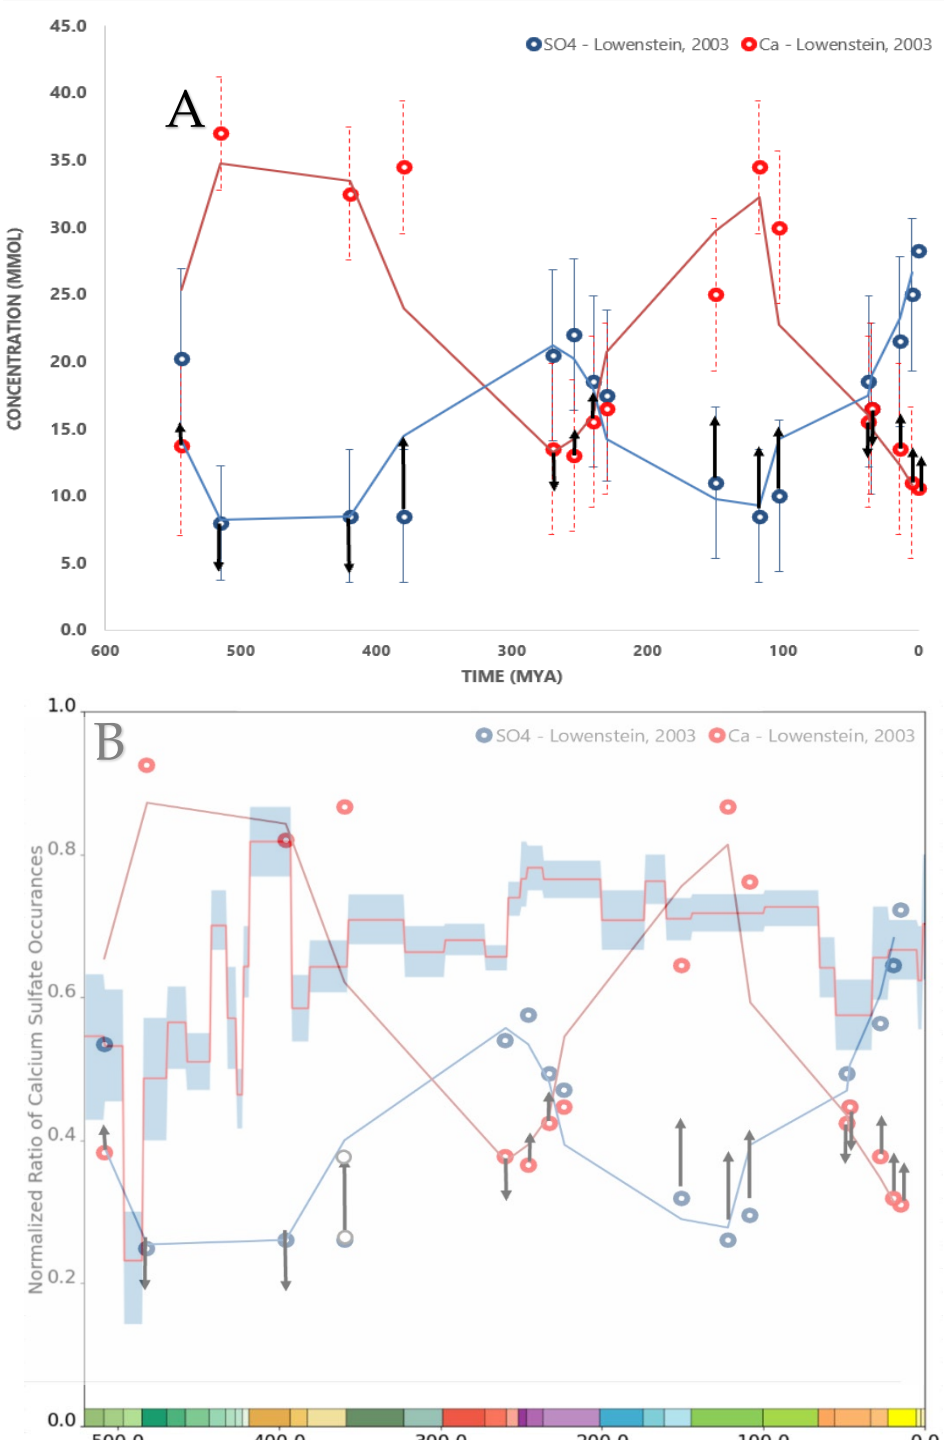

Figure 5.1: Plots showing the quantitative estimate of seawater chemistry and RAC throughout the Phanerozoic. (TOP) 5.1A Shows Sulfate and Calcium concentrations in mmol/L obtained through fluid inclusion analysis through Phanerozoic. (BOTTOM) 5.1B Shows the RAC through Phanerozoic with the fluid inclusion analysis of Lowenstein et al., 2003 overlain to show how this record could be used to infer calcium or sulfate concentrations in fluid inclusion analyses. Note that arrows plotted on 5.1A are qualitative estimates as to how the RAC could help constrain estimates of fluid inclusion data by narrowing the range of the product of $[Ca^{2+}]$ and $[SO_4^{2-}]$ and should be considered approximate.

5.3 Phanerozoic Abundance of Marine Evaporites

The results of this study could offer unique insights into the relationship between the occurrence of evaporite deposits and global sea-level fluctuations throughout the Phanerozoic era. The global record of sea-level change has been quantified using various proxies. Here I compare the evaporite data from Chapter 3 to a sea-level record from a new method based on using a "hypsometric slope", examining the areal difference of exposed vs. submerged landmass (Marcilly et al., 2022). This method allows for a reasonable quantification of submerged land mass in addition to sea-level that has been shown to provide reasonably good results when looking at time periods greater than 10 Mya (Algeo & Wilkinson, 1991). Other proxies provide a reliable metric to measure changes in paleo-sea-level, however, when looking at the results of the GDD text-mining application and Macrostrat records, a broader timescale resolution serves as a better comparison to gauge trends in the results of this study. Other methods have looked at a specific definition of "flooding" in terms of eustatic sea-level change, however Marcilly et al., (2022) has incorporated two methods that look at two definitions of "flooding". The first definition of "Modern Flooding" is "the areal difference between exposed land at a certain time in the past (exposed but moved in time according to the tectonic reconstruction) versus the total land area exposed today" (Marcilly et al., 2022). The second definition of flooding used to gauge the hypsometric slope gauge of eustatic sea-level change is "Continental Flooding". This is defined as the area of land exposed through time including continental shelve inundation and flooding along passive margins (Marcilly et al., 2022). As discussed further below, sea-level is expected to have a significant influence on evaporite formation and preservation in the geologic record due to its influence on the number of potential evaporite forming basing (e.g., shallow, repeatedly flooded, seaways).

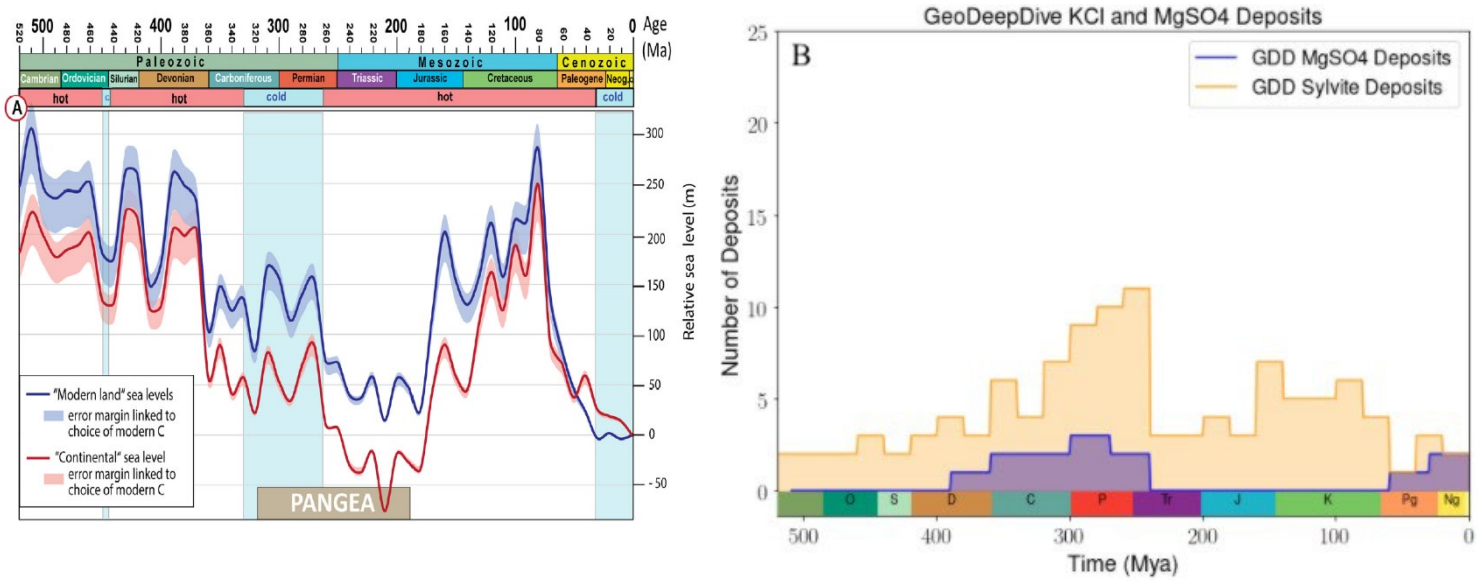

Figure 5.2: showing estimates of global sea-level over the Phanerozoic from Marcilly et al. (2022) (LEFT)) 5.2A based on" Modern" and "Continental" flooding. These are two methods of determining the relative coverage of submerged preserved sediments to exposed crust. 5.2B shows the occurrence of $MgSO_4$ and KCl throughout the Phanerozoic compiled from the GDD document set (RIGHT).

There appears to be a correlation between the abundance of potash evaporites and sea-level fluctuations (Fig 5.2) that I interpret as possibly providing evidence for the impact of eustatic sea-level changes on evaporite deposition. Both the new evaporite record developed here from GDD, and that of Hardie (1996) show that $MgSO_4$ and KCl abundance tends to increase during periods where there is significant continental flooding following a decrease relative sea level, then relative sea-level subsequently decreases again (Fig. 5.2). The presence of more evaporites that contain these late-stage minerals suggests that evaporite formation (and/or preservation) was more favorable during these intervals. Time intervals where sea-level is decreasing for a prolonged period of time would be an important factor influencing evaporite formation. Evaporite formation over the course of a large portion of geologic time would require

a closed or restricted basin where seawater recharge is needed to provide the ions to form an evaporite. Considering sea-level decrease, this would provide a mechanism where seawater has been flooded onto a continental basin or structure that is now cut off from seawater. Further decreases in sea-level would restrict the basin and allow for a full evaporite assemblage.

When examining changes in the amount of $CaSO_4$ evaporites formed after the Carboniferous, calcium sulfate becomes significantly more abundant than unique halite deposits (Figure 3.2) even though the largest number of halite and calcium sulfate deposits found within this study reside within the Permian (Figure 3.2). One of the primary drivers of widespread evaporite formation seems to be the relationship between sea level and the fraction of submerged landmass. When considering the ideal evaporite forming location it would involve some restricted marine basin that is periodically recharged or where evaporation of seawater exceeds the water recharge inputs. This could happen across widespread basins that are approximately the same level or slightly lower than sea level occurring on continental margins. To have widespread evaporite formation where deposits are characterized by their own unique stratigraphic association would either require an abundant area that is suitable for evaporite formation or a rapid sea level drop allowing the paleoseawater trapped in a depression to form an evaporite, thus forming when a significant portion of the continental area is flooded. This observation opens the door to using $CaSO_4$ deposits as proxies for quantifying the removal of calcium sulfate from seawater during specific geological time periods. In support of this notion, the interesting trend observed when comparing Figure 5.2A and Figure 3.3A shows that when there is a significant amount of continental flooding following a decrease in paleo-sea-level. Widespread continental flooding should correlate to a greater rate of evaporite formation and in comparing these two records, peaks in the RAC seem to correlate during widespread continental flooding,

suggesting that these time periods in geologic history could have a greater flux of ions removed as evaporite lithologies.

Summary and Future Work

The findings presented in this study offer a more comprehensive record of evaporites than has been available to-date and can be used to further understand the evolution of paleo-seawater. Changes in seawater chemistry have been modeled and evaluated to conclude the main driver of an increase of calcium sulfate evaporites is most likely an increase in the concentrations of Ca^{2+} or SO_4^{2-}. If the concentration of calcium or sulfate were higher during some periods of the Phanerozoic than others this could provide an explanation for the observed variation in the RAC (Figure 3.3A). When looking at a broader time resolution of the RAC, it appears that seawater chemistry has changed since the Mid-Devonian. Prior to the Mid-Devonian calcium sulfate occurrences were sporadic and highly variable where the RAC record following this change suggests paleo-seawater was more stable with respect to the concentrations of more of a stable system with respect of Ca^{2+} or SO_4^{2-}. These changes can be qualitatively evaluated and could suggest the product of Ca^{2+} or SO_4^{2-} was not constant throughout the Phanerozoic. Further constraining the RAC record using mass abundance of calcium sulfate to halite could aid in determining paleo-seawater composition change derived from fluid inclusions. Evidence for the influence of global sea-level changes on the occurrence of evaporite deposits is apparent in the secular occurrence of Macrostrat and GDD derived records of evaporite occurrences, including potash, calcium sulfate, and dolomite, in the stratigraphic record. These observations are consistent with models that sea-level change is a primary driver in the occurrence and temporal abundance of evaporites. These observations underscore the importance of sea-level reconstructions in understanding paleoenvironmental conditions and have broader implications

for seawater chemistry and global geological processes.

The results of the GDD text mining application, Macrostrat analysis, and PHREEQC modeling show that utilizing unstructured data can provide new mediums to analyze the changes in paleo-seawater throughout earth history. This study was limited in the scope of the text-mining model and future work should allow for a more comprehensive analysis with respect to the evaporite inventory by mass. Attempting to quantify the global extent of evaporite formation could provide a key insight into what processes can significantly influence seawater chemistry and allow for more accurate models constraining sources and sinks of the major ions in paleo-seawater. Future attempts should also consider the extraction of tabulated data within a scientific publication to a greater extent. Due to the limitations of the NLP parsing of documents contained within GDD valuable information that is not readily extractable using a model primarily driven by the in-text extraction of evaporite instances, geologic ages, and marine origins is lost. Advances in machine learning and computer vision should be utilized to allow for the extraction of tabular data within scientific publications and appears to be advancing rapidly. Although this addresses the extraction of data in more recent publications, there is a large majority of stratigraphic data contained in cross-sections and other geologic figures. These shortcomings with respect to tabular and figure data extraction are more difficult to address, however could be achieved with the advances observed in machine learning and computer vision.

Future work could also utilize the text-mining capabilities of GDD and text-mining models similar to this study to analyze the sulfur cycle and generate a global analysis of sulfur containing lithologies. Shales and other sediments abundant in reduced sulfur compared to oxidized sulfate found in evaporites could reconcile sources and sinks of sulfur throughout geologic history and should be investigated to contextualize the sulfur isotope record. Furthermore, the occurrence of

calcium sulfate evaporites could provide additional insight into the sulfur cycle, carbon cycle, or oxygen cycles as mechanisms that could cause the changes observed in calcium sulfate evaporite occurrences derived from GDD. Additionally, these changes could be explored to look at mechanisms of Dolomite formation throughout the Phanerozoic. Analysis of publications outside of GDD show there are a significant number of relevant articles contained within the journal of Economic Geology. The incorporation of this data set will provide more data, evaporite mentions, and an even greater record of evaporite bearing units. With the advent of advanced machine learning algorithms used to extract unstructured data and the continual grown of GDD, more advanced analysis should be performed in the future, deriving not only the occurrences of evaporite minerals through time but also aiding in constructing a global comprehensive database of the sedimentary and evaporite record.

Appendix A

Results obtained in the results of this research were tabulated in a Microsoft Excel workbook, however, are provided within the thesis as a PDF. Reach out via email to Benjamin.kumpf@gmail.com to obtain the Excel copy. The columns provided in the pdf version of Appendix 1 are described below:

- GeoDeepDive DocID to reference the source document for the extracted data;
- Sentence ID to identify which sentence the data came from;
- The stratigraphic name that a specific evaporite mineral was matched to in this research;
- The assigned Top Age of the stratigraphic unit;
- The assigned Bottom Age of the stratigraphic unit;
- Document Title;
- Journal Name;
- Journal Volume;
- Journal Publication Year;
- Publisher;
- Article DOI information.

This information is divided into 6 spreadsheets of which the first 5 correspond to the entries provided in Table 3.1. The spreadsheet name is located on the footer of each page. The sixth spreadsheet provides a list of hand filtered marine epsomite units that were manually evaluated and incorporated into Figure 3.1.
