Abstract

Color temperature relations and bolometric corrections are commonly employed not only to infer the physical properties of a star from its photometric color indices, but more importantly to translate stellar evolutionary tracks and isochrones from the theoretical temperature-luminosity plane to the observational color-magnitude plane. The current work discusses the efforts to develop a new and extensive grid of synthetic Strömgren colors applicable to cool, low mass stars (i.e., those having $3000 \text{ K} \leq T_{\text{eff}} \leq 8000 \text{ K}$, $-0.5 \leq \log g \leq 5.0$, and $-3.0 \leq [\text{Fe}/\text{H}] \leq +0.5$). These purely theoretical colors, based on the latest versions of the MARCS model atmosphere and SSG spectral synthesis codes, are placed onto the observational systems by applying color calibrations derived from the *uvby* photometry of field stars having accurate *Hipparcos* parallaxes and effective temperatures determined using the infrared flux method. The resultant color transformations are able to reproduce the observed colors of the classic Population II subdwarfs quite satisfactorily, as well as yield a very good fit of a 4 Gyr isochrone, whose T_{eff} scale is normalized to the Sun, to the observational color-magnitude diagram of the open cluster M 67. To supplement this investigation, recent photometric observations in the *uvby* filter system of the open clusters NGC 188 and NGC 6819 were obtained to further constrain the accuracy of the new Strömgren color-temperature relations for solar metallicities. Moreover, when the latest theoretical isochrones of Bergbusch & Vandenberg (2001) are transformed to the various Strömgren color planes, they provide superb fits to the CMDs of such globular clusters as M 92, M 13, NGC 288, and 47 Tuc when reasonable estimates for the basic cluster parameters (i.e. distance, reddening, and metallicity) are assumed.

Acknowledgments

While it seems such a trivial task to acknowledge those people who have supported and/or encouraged me throughout the time leading up to and including the writing of this thesis, I find it somewhat impossible to express how thankful I truly am to all of them on just a few pages. In truth, my appreciation goes well beyond whatever is written here, and I must emphasize that the people I list in the following paragraphs deserve much more recognition than I can rightly give them with just a few simple words on paper.

To those people who have made my research possible, I would foremost like to thank my supervisor, Don VandenBerg, for his insightful discussions, advice, motivation, guidance, and generous financial support during my study. His knowledge of stellar structure and evolution far outweighs anything which could be found in a textbook, and his enthusiasm towards my own research made the whole process more exciting (and even more bearable) for me. Also, I am indebted to Frank Grundahl who graciously provided the majority of superb photometric data used for this thesis, as well as his vast knowledge and many useful discussions on photometry and data reduction. Finally, much thanks is extended to Roger Bell of the University of Maryland for the use of the programs employed to generate the synthetic Strömgren colors.

Over the past three years, a number faculty and staff members here in the department have offered their words of advice and/or lended an ear when I needed to ask a question or vent some frustration. In particular, Russ Robb always had his door open and the time to listen to whatever I had to say. I would also like to thank Mr. David Balam (a.k.a. Uncle Dave) for every light-hearted, but wise, word of advice he has offered to me as well as having a sense of humor (slightly) more twisted than my own. In addition, his patience and guidance during my observing time at the Plaskett

telescope made the entire experience extremely rewarding and less stressful for me. To Stephenson Yang, I want to express my appreciation for all the time, energy, and devotion in keeping the computers operating smoothly here on the fourth floor of the Elliot Building.

Of course, I can't exclude (for concerns of my own personal safety) my fellow graduate students, both past and present, from this list - those people with whom I've shared many laughs, many beers, and many strange stories. I have to admit that despite the onslaught of jokes concerning my nationality, and particularly my home state - not to mention persistent attempts to assimilate me into the Canadian culture - no other group of people has made me feel more comfortable and more welcome during my stay in Canada. From Friday afternoon beer time to Mr. Gwyn's infamous boat drinks parties where anything that you couldn't possibly imagine happening, inevitably did, my life as a graduate student has been a fun and rather interesting one. To those people (and you know who you are), I want to extend my deepest gratitude.

On a personal level, I have been, and will forever be, indebted to my parents, Donald and Arlene Clem, for their endless love and support throughout my life. While they admittedly never fully understood what exactly I was studying at a Canadian university, they always were willing to provide whatever I needed to get me through the good - and not so good - times. Finally, and most certainly not the least, to the person who has shown much patience, sacrifice, understanding, and love to me throughout the time I have known her, I cannot truly express the amount of gratitude, appreciation, and love I have in my heart for you, Melissa. You have always been there to show an interest in what I was doing as well as lend a supporting and caring ear to my troubles and frustrations. I thank you for what you have done for me, and I am extremely happy to have had you as a part of my life for the past three years.

Chapter 1

Introduction

Given all the observational and empirical tools astronomers have at their disposal, the Hertzsprung-Russell (HR) diagram has proven to be one of the most valuable in our quest to understand the physical and evolutionary properties that govern the nature of stars. Ideally, the best way to ascertain a star's position within the HR diagram is to obtain high-resolution observations of the stellar spectral energy distribution and derive estimates for its basic physical properties such as effective temperature, surface gravity, and chemical composition (T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$, respectively). In practice, however, this method of study is very time consuming and feasible for only the brightest stars. For example, the idea of obtaining individual spectra for each member of a stellar cluster which could contain hundreds or thousands of stars would require an overwhelming amount of observing time (even assuming the stars are bright enough to get usable spectra). Thus, for the study of a large number of fainter objects, astronomers must resort to lower resolution techniques such as multicolor photometry. The method of photometry typically involves the use of filters to allow observations of an object to be made in specific wavelength regions. If the photometric system used is well designed and calibrated, it can provide an accurate means for investigating the physical characteristics of a multitude of stars where higher resolution data are not

available. One of the benefits of this type of study is the creation of the photometric equivalent to the HR diagram, the color-magnitude diagram (CMD). By plotting a star's color (i.e. the difference of its brightness through two different filters) versus its magnitude, the resulting CMD still retains the same basic information as an HR diagram, but obtained with much less time and effort.

1.1 The Strömgen Photometric System

Among all the photometric systems available today, the two most widely used are the *UBV* system of Johnson and Morgan (1953) and the *uvby* system of Strömgen (1963). While both systems were born out of the desire to develop a framework for classifying stars on the basis of photoelectric indices, certain aspects of the *uvby* system set it apart from its *UBV* counterpart. Namely, the four Strömgen filters (*u*, *b*, *v*, and *y*) are characterized by their intermediate bandwidths ranging from 180 to 300 Å as compared to the broader ($\approx 700\text{-}950$ Å) *UBV* filters. Table 1.1 lists the specifics regarding the central wavelengths, bandwidths, and transmissions for the two filter sets whereas Figure 1.1 plots a comparison of their location and spectral coverage.

As seen in the figure, the four Strömgen filters sample the same spectral region as the broadband system, only more finely. The narrowness of each filter together with their wide spectral coverage as a whole gives the *uvby* system several advantages over the broader *UBV* filters. The Strömgen *y* (yellow) filter is centered in the middle of the visual part of the electromagnetic spectrum and closely corresponds to the Johnson *V* filter. Indeed, early calibrations showed that stellar magnitudes determined through the Strömgen *y* filter can be equated to *V* in photometric studies. Also, the filter transmits no strong spectral features in stars of most spectral types. Likewise, the *b* (blue) filter sits in a region where the effects of line absorption are not particularly strong for early type stars. The next filter, *v* (violet), is positioned

Table 1.1: The filters used to define the *uvby* and *UBV* photometric systems. All information presented in this table as well as the filter response functions plotted in Figure 1.1 are taken from Crawford & Barnes (1970b) and Strömgren (1963) for the *uvby* filters and Johnson & Morgan (1951) for the *UBV* filters.

Filter	Central Wavelength (Å)	Bandwidth (Å)	Maximum Transmission (%)
<i>u</i>	3500	300	44
<i>v</i>	4110	190	46
<i>b</i>	4670	180	47
<i>y</i>	5470	230	52
<i>U</i>	3600	690	60
<i>B</i>	4400	960	55
<i>V</i>	5500	900	43

above the Balmer discontinuity limit in a region which is strongly affected by line blanketing in stars of all spectral types. Finally, the *u*, or ultraviolet, filter is confined completely within the region defined by the Balmer discontinuity to the red and the cutoff imposed by the Earth's atmosphere at shorter wavelengths.

To illustrate how the Strömgren filters serve to isolate important features in a stellar spectrum, Figure 1.2 presents a synthetic spectrum of a normal main sequence star of spectral type F 5 and its corresponding theoretical continuum represented by a dotted line overplotted with spectral coverage of each *uvby* filter from Table 1.1. From the locations of the *b* and *y* filters it is obvious that neither filter suffers from any significant absorption features. Therefore, it follows that the color index ($b - y$) is particularly insensitive to the effects of line absorption in this portion of the spectrum and can be considered as an accurate estimator of continuum slope. For this reason, the ($b - y$) index is a good indicator of stellar effective temperature (T_{eff}) akin to the ($B - V$) index in broadband photometry.

The same does not hold true for the difference in flux between the *v* and *b* filters, however. The ($v - b$) index is strongly affected by the prominent absorption features

Figure 1.1: The transmission curves of the Strömrgren *uvby* filter set compared to the *UBV* filters of Johnson & Morgan.

in the v band. Thus, a new quantity $m_1 [(v - b) - (b - y)]$ is defined to measure the intensity of the line blanketing in the v filter relative to the color gradient in the b and y regions. Indeed, the Strömgen m_1 index is generally considered to be an accurate photometric measurement of the abundance of heavy elements (i.e. elements heavier than helium) in a star's atmosphere due to the fact that a higher abundance of metals results in increased absorption in the v band. In his seminal paper discussing the benefits of the $uvby$ system, Strömgen (1966) presented a simple correlation between m_1 and the stellar abundance parameter, $[\text{Fe}/\text{H}]$. While his analysis was based on only a few main sequence stars, it presented the first real evidence that m_1 could successfully be calibrated against $[\text{Fe}/\text{H}]$. Since that time, numerous such calibrations for both main sequence and giant stars have surfaced in the literature (e.g., see Schuster & Nissen 1989 and Hilker 2000 and references therein) which report both well defined and consistent relations between photometric and spectroscopic abundance determinations.

As mentioned earlier, the Strömgen u filter lies almost completely below the Balmer discontinuity at 3647 Å. For this reason, the $(u - v)$ index can be considered as a measurement of both the height of this discontinuity plus the fraction of line blanketing as measured by the $(v - b)$ index. Taking the difference between these two color indices leads to the quantity $c_1 [(u - v) - (v - b)]$ which accounts solely for the size of the Balmer jump and is commonly considered to be an accurate indicator of stellar surface gravity in most stars (specifically mid-B to early-G type stars). A star's gravity (commonly expressed logarithmically as $\log g$) is dependent on its evolutionary state. Main sequence stars (classes IV and V in the Morgan-Keenan classification scheme) have the highest values for $\log g$ while giants (classes I, II, and III) of the same spectral type typically have much smaller values due to their large size. A difference in $\log g$ correlates with Balmer discontinuity because the size of the jump is less in giants than in main sequence stars due to pressure effects. As with the m_1 parameter, Strömgen recognized the usefulness of the c_1 index in distinguishing

Figure 1.2: The spectral coverage of each *uvby* filter overplotted on a theoretical spectrum corresponding to an F5 V star to illustrate how each filter isolates certain important spectral features. The dotted line represents the theoretical continuum level of a star of the same spectral type.

between giants and dwarfs having the same spectral type, and a number of studies have addressed the $c_1 - \log g$ correlation both theoretically (Relyea & Kurucz 1978 and Moon & Dworetsky 1985) and observationally (Castelli 1991 and Napiwotzki et al. 1993) .

In summary, the Strömgen *uvby* photometric system can provide precise photometric estimates of star's effective temperature, surface gravity, and chemical composition via the definition of the $(b - y)$, m_1 , and c_1 color indices, respectively. It is this ability that sets Strömgen intermediate-band photometry apart from standard broadband *UBV* photometry. The broadness of the *UBV* filters greatly limits the amount of information that can be obtained photometrically for a star. While the $(B - V)$ index is quite similar to the Strömgen $(b - y)$ index in providing T_{eff} information, it cannot be used (like the m_1 index) to infer the metallicity of a star. Furthermore, the four color system is almost completely filter defined and is barely affected by detector sensitivity or atmospheric limitations. The same cannot be said for the broadband *U* filter, which can be compared to the Strömgen *u* filter through the fact that they are both centered at roughly the same wavelength and the $(U - B)$ index can be used to estimate the size of the Balmer jump. Due to its large bandwidth, however, it is not fully contained between the Balmer discontinuity to the red and the atmospheric cutoff towards shorter wavelengths like the *u* filter, and photometric observations and reductions involving the *U* filter are affected by both the instrumentation and observing location.

Despite all of the advantages and potential that the Strömgen *uvby* system brings to our understanding of the nature of stars, many researchers still adopt the *UBV* filters as their photometric system of choice. This fact can likely be attributed to the following reasons. First, observations using the *uvby* filters typically require longer integration times due to their narrower bandwidths. This problem has been mostly overcome, however, with the modern use of CCD detectors which offer both superb sensitivity over a wide spectral range and the ability to simultaneously observe a

large number of stars within the same field compared to the older photon counting instruments which were limited to observing one star at a time. Second, in order to use the Strömgren system to its full potential, observations should be made through each of the four *uvby* filters. This, along with the aforementioned longer integration times, poses a problem for astronomers who are limited by their observing time budget, and many may choose to sacrifice the information which could be obtained using the four-color system for the expedience of the *UBV* filters. The final reason derives from the fact that direct comparisons of theoretical stellar models to Strömgren photometric data have been difficult in the past owing to the lack of modern and precise *uvby* color-temperature relations and bolometric corrections which are needed to transform these models to the observations. While this problem will be addressed in detail throughout the present work, it suffices to say here that this current inability to accurately relate theoretical models to *uvby* data is a significant reason why the *UBV* system has remained the dominant photometric system for observers and theorists.

1.2 The Role of Color-Temperature Relations

One area where astronomical photometry plays a crucial role is the study of star clusters. These stellar populations are composed of multitude of stars with a wide range in mass but with essentially the same age and chemical composition. For this reason, clusters and their associated photometric CMDs offer ideal testing grounds for many aspects of stellar evolution theory. The most popular way to compare the theory with photometric observations is by computing numerous stellar evolutionary tracks as a function of mass, determining a position on each track corresponding to a specific age, and comparing the resulting curve connecting these positions (i.e. an *isochrone*) to the actual distribution of stars in a cluster CMD. This so-called “isochrone fitting” technique has been widely used in the past to not only test the overall accuracy of the stellar models, but also to yield estimates for the cluster’s

distance, reddening, and age provided an isochrone modeled with the same chemical composition as the cluster is employed.

However, there is a crucial step in this type of confrontation between theory and observations. Specifically, how do the model evolutionary tracks and isochrones, computed in terms of stellar temperature and luminosity, get transferred to their observational equivalents of photometric color and magnitude? For this purpose, a set of predefined color-temperature (C-T) relationships and bolometric corrections (BCs) are required to link photometrically determined indices with the fundamental stellar parameters of effective temperature, surface gravity, and chemical composition. In a time when extremely precise cluster photometry and recent stellar models which account for the most up-to-date physics are becoming readily available, these C-T relations and BCs play an increasingly important role in bridging the gap between theory and observation. Not only are extremely precise and consistent relations needed to check the accuracy of the stellar models in interpreting photometric data, but they must also ensure that reasonable estimates for a star's T_{eff} , $\log g$, and chemical composition can be obtained from just knowing its photometric indices.

Typically, C-T relations and BCs for any photometric system can be derived by using either theoretical or empirical methods. Whereas theoretical grids of synthetic colors are produced by convolving models of photometric filter transmission profiles with synthetic spectra of stars having a wide range of effective temperatures, surface gravities, and chemical compositions, empirical methods rely on calibrating photometric colors against stars having precise estimates for their basic parameters. Both methods have their advantages and disadvantages. For instance, the production of large grids of theoretical colors are ideal for transforming isochrones and evolutionary tracks to the observational plane owing to the fact that a color and magnitude can be readily computed for any stellar model. However, the accuracy of the synthetic colors tend to rely on how well the input synthetic atmospheres and spectra are able to reproduce the observed spectrum of an actual star. Empirical C-T relations, on the

other hand, overcome this problem because they are largely model independent, but they are restricted to a very limited sample of stars with well-determined values for T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$. While some considerable effort has been devoted over the years to deriving such C-T relations for the Strömgen system using both techniques (see, e.g., the discussions of Relyea & Kurucz 1978, Moon & Dworetzky 1985, Vandenberg & Bell 1985, Kurucz 1991, Gratton et al. 1996, and Alonso et al. 1996b), and the results appear to show reasonable agreement for some cases (often for warmer effective temperatures) but usually fail to reproduce the photometric data to a high degree of accuracy over the entire range in temperatures; a fact that is generally exemplified by inadequate isochrone fits to cluster *uvby* CMDs (Grundahl et al. 1998, 2000).

1.3 Scope of the Present Study

Given that currently available C-T relations and BCs for the *uvby* system appear to provide a limited degree of success in relating stellar evolutionary models to *uvby* observations, this study undertakes the task of deriving a new, more extensive, and internally consistent grid of synthetic Strömgen colors on the basis of theoretical stellar spectra but constrained to satisfy empirical data. While Chapter 2 outlines the basic concepts and programs involved in computing the theoretical Strömgen colors, Chapter 3 will seek to constrain the accuracy of the resultant synthetic colors by testing them against a number of field stars with well-determined values for T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ and accurate *Hipparcos* parallaxes. Chapter 4 will serve two purposes. First, the testing of the theoretical Strömgen colors will continue by transforming a number of isochrones to the observational color-magnitude plane and fitting them to the *uvby* CMDs of a large sample of open and globular clusters with various ages and metallicities. Secondly, the consistency between such fits to the four color CMDs and those obtained from broadband CMDs will be investigated to determine whether or not the same isochrone yields the same interpretation of the data regardless of which

photometric color is used. Finally, concluding remarks are presented in Chapter 5.

Chapter 2

The Synthetic Colors

In any ground-based photometric system light from a star passes through the Earth's atmosphere, is reflected by the optics in a telescope, passes through a filter, and is collected at the focal plane by a photon detecting device. To allow intercomparisons of observations made using different equipment (i.e. telescopes, filters, and detectors), a number of stars are observed that have colors defined on a standard system. The observed data are then transformed to the standard system by forcing the standard and observed colors to agree. In order to generate a set of synthetic colors, one must not only be able to model the spectrum of a star, but also construct a theoretical photometric system which accurately accounts for all of the principles mentioned above (such as the transmission of the atmosphere, the reflectivity of the telescope mirrors, transmission of the filters, sensitivity of the detector, and the adoption of suitable standard stars).

The following chapter outlines the basic ideas and procedures involved in constructing a set of synthetic Strömgren colors via the following steps: 1) Create a unique theoretical model atmosphere corresponding to a star having a specific effective temperature, surface gravity, and chemical composition (T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$, respectively), 2) employ this model atmosphere in the generation of a synthetic stel-

lar spectrum, and 3) convolve the resulting synthetic spectrum with the response functions of the *uvby* filters. Repeating these steps for a number of stellar models covering a wide range in temperature, gravity, and abundance results in a composite grid of synthetic colors suitable for either transforming theoretical stellar models to the observational plane or estimating the basic properties for a star basely solely on its observed photometric indices.

2.1 Stellar Atmosphere Models

The MARCS program (Gustafsson et al. 1975) has been widely used in the past for the construction of model stellar atmospheres. The current version of the MARCS program computes a flux-constant, homogeneous, plane-parallel atmosphere assuming hydrostatic equilibrium and local thermodynamic equilibrium. The solar abundance scale adopted for the models follows that given by Anders & Grevesse (1989) with small modifications to the carbon and nitrogen abundances reported by Grevesse et al. (1990, 1991). Furthermore, enhancements to the α process elements (O, Ne, Mg, Si, S, Ar, Ca, and Ti) by +0.4 dex relative to the solar value were considered for models with $[\text{Fe}/\text{H}] \leq -1.0$ and +0.25 for $[\text{Fe}/\text{H}] = -0.5$. For models with solar and super-solar abundances, no α enhancements were considered in the mix. These enhancements in the model atmospheres reflect recent spectroscopic evidence (Zhao & Magain 1990, Kraft et al. 1998, and Carney 1996) which suggest an overabundance of the α elements relative to solar (commonly denoted as $[\alpha/\text{Fe}]$) of at least +0.3 dex is present in the most metal poor halo and globular cluster stars. Table 2.1 presents the chemical abundance mix adopted for not only the MARCS atmospheres, but also for the generation of the synthetic spectra which will be described in the next section.

The tabulated values listed in Table 2.1 are given on the logarithmic scale usually adopted by astronomers in which the abundance of each element is expressed relative to the number abundance of Hydrogen by $A_{el} = \log N_{el}/N_H + 12.0$. Elements marked

Table 2.1: Solar elemental abundances considered in the generation of the model atmospheres and synthetic spectra taken from Anders & Grevesse (1989) with small modifications to the abundances of C and N given by Grevesse et al. (1990, 1991). Elements flagged by double asterisks are those required as input to the MARCS atmosphere program.

Element	Abundance	Element	Abundance	Element	Abundance

by double asterisks indicate those abundances which are required as input in the MARCS program. MARCS accounts for atmospheres with differing chemical compositions by multiplying all abundances except H and He by $10^{-0.5}$, 10^{-1} , 10^{-2} , etc. to obtain the metallicities denoted by $[M/H]^1 = -0.5$, -1.0 , and -2.0 , respectively.

The treatment of convective energy transport in the atmospheric models follows the variant of the mixing-length theory given by Henyey et al. (1965). For all models, the mixing length ℓ was set to a value of 1.6 the pressure scale height H_p ($\ell = 1.6H_p$). Furthermore, the y parameter describing the transparency of convective bubbles was set to $3/(4\pi^2) \approx 0.076$ which corresponds to the temperature structure of a convective element that results from the diffusion approximation.

The MARCS program incorporates opacity distribution functions (ODFs) to represent the opacity due to atomic and molecular lines as a function of wavelength. The specifics regarding the concepts and construction of ODFs are explained extensively in Gustafsson et al. (1975, sec. IIIb). For the sake of brevity, however, only a basic outline of how MARCS uses an ODF to compute a model atmosphere will be presented here. The ODFs are produced from the latest lists of spectral lines which contribute significantly to the line opacity. In general, an ODF is set up in the form of a look-up table for interpolating the opacity in a certain wavelength region as a function of both the temperature and electron pressure derived from MARCS. Obviously, a different ODF must be computed for different chemical abundance mixes (i.e. different metallicities) owing to the fact that a higher abundance would mean that the overall line spectrum will be richer.

¹Past literature devoted to theoretical atmosphere studies typically adopt $[M/H]$ or $[A/H]$ to logarithmically express the number abundance ratio of *all* metals to hydrogen relative the sun. However, the most convenient way of quantifying a star's chemical composition observationally is its iron to hydrogen abundance ratio relative to the sun, or $[Fe/H]$. While there are distinct differences between these two values, both in their meaning and function, they will be used interchangeably throughout the present work to refer to the "metallicity" of a star and/or model.

2.2 The Synthetic Spectra

The SSG spectral synthesis code (Bell & Gustafsson 1978, 1989) uses the generated MARCS stellar atmosphere together with spectral line data, a Doppler broadening velocity (which includes both a thermal and microturbulent term), and the elemental abundances presented in Table 2.1 to compute a synthetic stellar spectrum. The synthetic spectra presented here have been computed at 0.1 Å resolution covering an optical wavelength range of 3000 - 8000 Å. SSG uses the most up-to-date atomic and molecular line lists (described in Bell et al. 1994) together with an additional TiO line list for all spectra with $T_{\text{eff}} \leq 4000$ K to accommodate for the increased strength of TiO molecular absorption features in cool stars (Houdashelt et al. 2000). Furthermore, the microturbulent velocity, ξ , is assumed to vary as a function of surface gravity using the relation $\xi = 2.22 - 0.322 \log g$ (Gratton et al. 1996). To account for the continuum opacity due to H^- , SSG assumes the Wishart (1979) and Bell & Berrington (1987) bound-free and free-free cross-sections for the H^- ion, respectively.

2.3 Synthetic Photometry

As mentioned at the beginning of this chapter, the process of computing synthetic magnitudes and colors typically involves using a synthetic stellar spectrum as input into a theoretical photometric system. This system convolves the spectrum with not only the transmission profiles for a specific filter set, but also the detector sensitivity function, and an atmospheric extinction profile. By definition, the computed magnitude m_i for a particular filter or passband is given by:

$$m_i = -2.5 \log \int_{\alpha_i}^{\beta_i} F_\lambda S_i(\lambda) A(\lambda) d\lambda, \quad (2.1)$$

where F_λ is the computed monochromatic flux at the stellar surface, $S_i(\lambda)$ is the sensitivity function describing the fraction of the star's flux that is detected at wavelength

λ ,² $A(\lambda)$ is the transmission of Earth's atmosphere, and α_i and β_i give the wavelength interval of $S_i(\lambda)$. From this formalism the photometric color indices are simply expressed as the difference between the magnitude of a star in two different spectral regions (i.e. through two different filters i and j). However, the synthetic indices cannot be directly compared to the observed indices of a star due to the fact that the computation of synthetic magnitudes involve the flux at the stellar surface, whereas observed stellar colors always involve apparent magnitudes. In practice, each computed index can correctly be related to the corresponding observed index by means of an additive constant:

$$(m_i - m_j)_{obs} = (m_i - m_j)_{calc} + C. \quad (2.2)$$

The most practical way to derive this constant C is by forcing a fit between computed and observed colors for a given star or sample of stars well reproduced by the stellar models.

A bolometric correction BC_i is described as the correction required to reduce a magnitude in a given bandpass to a bolometric magnitude. In other words, the computed BC_i is:

$$BC_i = (m_{bol} - m_i)_{calc} + K, \quad (2.3)$$

where, by definition, m_{bol} is the apparent magnitude of a star measured over all wavelengths:

$$m_{bol} = -2.5 \log \int_0^\infty F_\lambda d\lambda = -2.5 \log(\sigma T_{eff}^4). \quad (2.4)$$

Thus, the bolometric correction BC_V relative to the broadband Johnson V magnitude reduces to:

$$BC_V = -2.5 \left[\log(\sigma T_{eff}^4) - \log \int_{\alpha_V}^{\beta_V} F_\lambda S_V(\lambda) A(\lambda) d\lambda \right] + K. \quad (2.5)$$

where the constant K is required to match the adopted solar BC_V .

² $S_i(\lambda)$ can include such factors as the transmission of the photometric filters and other optical components used, the detector response, and the reflectivity of the telescope mirrors.

The IRCONVABS program serves as the virtual photometric system which is employed to calculate the synthetic Strömgen photometric indices and bolometric corrections given a theoretical stellar spectrum as input. IRCONVABS proceeds to compute the *uvby* magnitudes, color indices, and bolometric corrections by convolving the spectrum with the *uvby* filter transmission curves given by Crawford & Barnes (1970b) while accounting for atmospheric extinction due to Rayleigh scattering by molecules and scattering by aerosols using the treatment of Hayes & Latham (1975). At wavelengths longward of 7600 Å the effects of terrestrial line absorption are also included by considering the Manduca & Bell (1979) computations of Kitt Peak winter extinctions.

As a final step, the synthetic colors must be related to the observed Strömgen system by forcing agreement between the observed and calculated indices for a standard star. The most common way of doing this is to construct a synthetic flux model for a suitable standard like Vega, which is assumed to have $T_{\text{eff}} = 9650$, $\log g = 3.90$, and $[\text{Fe}/\text{H}] = 0.0$ (Dreiling & Bell 1980), and then compare it to the observed flux distribution. A significant amount of work has been devoted to this type of comparison (see, e.g., the discussions of Dreiling & Bell 1980 and Castelli & Kurucz 1994), and good agreement between the models and the data has generally been found. A set of zero point corrections, defined as the difference between the observed and calculated color indices for Vega, can then be applied to each subsequent set of colors to ensure they correspond to observational Strömgen colors.

The final composite grid of synthetic Strömgen colors computed using the programs and methods mentioned above covers a range in T_{eff} from 3000 to 8000 K in 250 K intervals and $\log g$ from -0.5 to 5.0 in increments of 0.5 dex for the abundances of $[\text{M}/\text{H}] = -3.0, -2.5, -2.0, -1.5, -1.0, -0.5, 0.0,$ and $+0.5$. While this particular grid is only applicable to cool, low mass dwarf and giant stars, an extension of the colors to higher temperatures is accomplished by melding this grid with

the synthetic Strömgren colors computed by F. Castelli at a temperature of 8000 K³. Furthermore, the bolometric corrections derived by P. R. Wood & M. S. Bessell (1994, private communication) from the Kurucz (1993) synthetic spectra are favored over those computed here in order to ensure consistency when comparing isochrone fits on various Strömgren CMDs with those presented in Vandenberg (2000) on various broadband CMDs.⁴

³The entire grid of Strömgren colors, based on a revised treatment of convection in the ATLAS9 model atmospheres discussed by Castelli et al. (1997), are currently available only on the homepage of R. L. Kurucz <http://cfaku5.harvard.edu>

⁴Indeed, the bolometric corrections derived here from the MARCS-SSG models show good agreement with those of Wood & Bessel in a systematic sense. The only mentionable differences between the two lie in a small zero point offset due to the adoption of slightly different normalization values for the sun.

Chapter 3

Calibrating and Testing the Synthetic Colors

The first step in testing the accuracy of the synthetic Strömgren colors is to assess how well they reproduce the observed colors of stars having various temperatures, gravities, and metal abundances. To facilitate this, one may use the colors to transform a theoretical isochrone to the observational plane and compare it to the color-magnitude diagram (CMD) of a cluster of stars. The two main purposes of fitting an isochrone to photometric data are check to the consistency of the theoretical models with the observations when best estimates of the cluster distance, reddening, and metallicity are assumed, and to derive the cluster age. However, inaccuracies in the synthetic colors as well as in the stellar models (due, for example, to the treatment of convection or the atmospheric boundary conditions) could easily lead to poor fits to the CMDs. Also, in clusters younger than ≈ 5 Gyr, the morphology of the main sequence turnoff is highly sensitive to the effects of convective overshooting in the stellar interior. Thus, it is important to first test the colors by using stars in the solar neighborhood having accurate parallaxes, low reddenings, and spectroscopically determined abundances. When the colors are constrained in this way, they should

not be a large source of error in the CMD fits.

This chapter will discuss how the Strömgren colors measured directly from synthetic spectra are tested using a sample of local field stars selected from the literature which have accurate *Hipparcos* parallaxes and well-determined effective temperatures, surface gravities, and metallicities. By comparing the calculated colors with the actual photometry for these field stars, a set of color calibrations are derived and used to correct the synthetic colors so they may be placed onto the observational system.

3.1 Synthetic Color Calibrations

The method of correcting synthetic colors by deriving a set of color calibrations from a sample of field stars with well-determined physical properties was most recently described by Houdashelt, Bell, & Sweigert (2000b, hereafter HBS). While their work was concerned with various broadband (*UBVRIJHK*) colors, their techniques can be easily adapted to calibrate the synthetic Strömgren indices. Two major differences between the present work and that of HBS should be mentioned. First, this work not only makes use of the sample of field stars employed by HBS (their Table 2), but also greatly expands on this list by including stars from Alonso, Arribas, & Martínez-Roger (1996, hereafter AAM96) and Alonso, Arribas, & Martínez-Roger (1999, hereafter AAM99). All of the stars in these three samples effectively cover the temperature, gravity, and metallicity range of the synthetic Strömgren colors presented here (see Figure A.1). Furthermore, reasonably accurate estimates of T_{eff} for these stars have been derived using the infrared flux method (IRFM) of Blackwell & Shallis (1977). Since effective temperature is the most crucial determinant of stellar color, it is important to have a stellar sample whose temperatures have been determined in an accurate and self-consistent way. Second, HBS choose to calculate an individual synthetic spectrum for each star in their list and use that spectrum to

derive the model colors. While this is certainly valid and feasible for the moderate number of field stars in their sample, the final list (see Table A.1) presented in this work contains over 500 field stars, and it would be impractical to compute individual model atmospheres, synthetic spectra, and colors for the entire sample presented here. Thus, Strömgren colors for each star in the listed in Table A.1 having a particular T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ are calculated by interpolating in the composite grid of synthetic colors.

To illustrate the need for these color calibrations, CMDs of the Galactic open cluster M 67 overplotted with a 4 Gyr, near-solar metallicity isochrone (see Vandenberg & McClure, in preparation) are presented in Figure 3.1. The *uvby* photometry for M 67 is provided by F. Grundahl (private communication) and has been corrected for a reddening of $E(b-y) = 0.029$ (corresponding to $E(B-V) = 0.04$ derived from the reddening maps of Schlegel et al. 1998). A slight sub-solar metallicity of $[\text{Fe}/\text{H}] = -0.04$ is adopted for the cluster which is consistent with recent spectroscopic studies (Tautvaisiene, Edvardsson, & Tuominen 2000 and Shetrone & Sandquist 2000). Finally, the absolute magnitudes of the M 67 stars are derived assuming a distance modulus of $(m-M)_V = 9.60$ (Nissen et al. 1987, Montgomery et al. 1993, Dinescu et al. 1995, and Fan et al. 1996). The 4 Gyr isochrone has been transformed to the indicated color planes in the figure by interpolating in the final, uncalibrated grid of synthetic colors for the set of temperature-gravity combinations lying along it.

While the isochrone appears to match the data quite well for the $(b-y)$ index if a small redward shift were applied, the fits to the data on the $(v-b)$ and $(u-v)$ color planes are not very satisfactory. It is difficult to ascertain what might be causing such discrepancies between the isochrone and the CMDs and why the colors measured directly from the synthetic spectra do not appear to be on the same system as the photometric data. Indeed, as mentioned earlier, errors in the isochrones could lead to a mismatch between models and the data. However, similar isochrone fits to M 67 in the broadband (*UBVRI*) system yield very acceptable fits to all components of

Figure 3.1: Strömgren photometry of stars in the open cluster M 67. The colors have been corrected for reddening and distance by the values indicated in the plots. The 4 Gyr, $[Fe/H] = -0.04$ isochrone overlaid on the CMDs has been transformed to the various color planes using the uncalibrated colors derived directly from the synthetic spectra.

the M67 CMD (see HBS). Ruling out possible errors in the model isochrones, the only other possible explanation are inaccuracies in the synthetic colors. To expand on this problem, Bessel et al. (1998) have touched on possible reasons why synthetic photometric colors fail to match their observed counterparts and conclude that, “As the standard systems have been established from natural system of colors using linear and nonlinear corrections of at least a few percent, we should not be reluctant to consider similar corrections to synthetic photometry to achieve good agreement with the standard system across the whole temperature range of the models.”

3.1.1 The $(b - y)$ index

To begin the calibration of the synthetic colors, Strömgren photometry for the field stars listed in Table A.1 has been compiled from the *uvby* catalog of Hauck & Mermilliod (1998). In addition, parallaxes and broadband colors for the entire sample are taken from the *Hipparcos* catalog (Perryman et al. 1997)¹. Finally, the effects of reddening on the field star photometry cannot be ignored despite the fact that all of them are relatively nearby. Therefore, the *uvby* colors for stars listed by AAM96 and AAM99 have been corrected for reddening by the $E(B - V)$ values² provided in their studies, whereas stars taken from HBS were reddening corrected by obtaining individual $E(B - V)$ values from the reddening maps of Schlegel et al. (1998) and multiplying by a factor $[1 - \exp(-|d \sin b|/h)]$, where d is the star’s distance, b its galactic latitude, and h the scale height of the typical dust layer, which was assumed to be 125 pc (Bonifacio et al. 2000).

Figure 3.2 presents the plot of the synthetic versus observed $(b - y)$ indices for the 541 stars listed in Table A.1. Stars in the plot are divided into two classes according to

¹Both catalogs were accessed online via the *VizieR* database at the Canadian Astronomical Data Center at <http://vizier.hia.nrc.ca/viz-bin/VizieR>.

²The $E(b - y)$ values listed in Table A.1 are derived assuming $E(b - y) = 0.732 E(B - V)$. Therefore, it follows that the reddening corrected Strömgren indices take the form $(b - y)_o = (b - y) - E(b - y)$, $m_o = m_1 + 0.347 E(b - y)$, and $c_o = c_1 - 0.228 E(b - y)$ (Schlegel et al. 1998).

their surface gravities. Filled circles represent dwarf and subgiant stars ($\log g \geq 3.5$), while open circles are the giants and supergiants ($\log g < 3.5$). In addition, the equality between the synthetic and photometric indices is indicated by the dashed line. From initial inspection, the plot shows that the synthetic ($b-y$) colors appear to adequately reproduce the observed colors for these field stars over a broad color range. Fitting a least-squares relation (solid line) to the field star data using the photometric color as the dependent variable and the synthetic color as the independent variable, the result does in fact show that the relation between the two is approximately equal if a small zero point difference is applied. This result is also evident in the left-hand panel of Figure 3.1 where the isochrone fit to the M 67 ($b-y$) CMD appears to follow the same trend as the photometric data from the main sequence through the giant branch, but doesn't quite adequately match due to an apparent small difference in color.

3.1.2 The m_1 index

Owing to the importance of the Strömgen m_1 index in providing a photometric indicator of stellar metallicity, it is imperative for the synthetic m_1 colors to accurately reproduce their observed counterparts. Therefore, following the same procedure mentioned in the previous section, Figure 3.3 presents the resulting plot of synthetic versus observed colors for the Strömgen m_1 index. However, this index is somewhat more problematic and shows a significant systematic deviation between the synthetic and observed colors for the field stars. This deviation is consistent with the discrepancy between the isochrone and the M 67 CMD shown in the middle panel of Figure 3.1. Given that the m_1 index contains the Strömgen v filter [recall $m_1 = (v-b) - (b-y)$; see Chapter 1], which is located in a heavily line blanketed region of stellar spectra, the synthetic spectra used to calculate the models colors may not fully account for the number of atomic and molecular lines in this region, thus underestimating the

Figure 3.2: The synthetic versus observed colors for the $(b-y)$ index. Filled circles represent all dwarfs stars from the field star sample with $\log g \geq 3.5$, and open symbols are all giants and supergiants ($\log g < 3.5$). The solid line gives the linear, least-squares fit to the data which is required to put the synthetic colors onto the observational system, whereas the dashed line represents the one-to-one relation between the synthetic and photometric colors.

amount of absorption in the v filter. This would systematically shift the colors bluer for cooler stars. Whatever the reason, the focus of this study is to determine the best way to derive the calibration necessary to put the synthetic m_1 colors onto the observed system rather than delve into the source of the problem.

By inspection of Figure 3.3, it appears that the dwarf stars in the sample follow a different trend than the giant stars. Furthermore, the coolest dwarf stars show a hint that a higher order polynomial may fit the data better than a straight line. To elaborate on this, Figure 3.4 divides the field stars into different temperature and gravity regimes in an effort to derive a separate and distinct color calibration for each set of stars. The stars classified as “warm dwarfs” ($5250 \text{ K} \leq T_{\text{eff}} \leq 8000 \text{ K}$; $\log g \geq 3.5$) are plotted in the left-hand panel of Figure 3.4. As illustrated in this panel, a simple least-squares relation appears to fit the data reasonably well. Stars identified as “cool dwarfs” ($3000 \text{ K} \leq T_{\text{eff}} \leq 5500 \text{ K}$; $\log g \geq 3.5$) and the “giants” ($3000 \text{ K} \leq T_{\text{eff}} \leq 8000 \text{ K}$; $\log g < 3.5$) are given in panels (b) and (c), respectively. While there is a rather large scatter in the data for the giants, another linear fit is used to calibrate their colors, whereas a second order polynomial is employed to fit the cool dwarfs. Stars excluded from the m_1 color calibrations due to their anomalous locations in the plots are indicated as asterisks. The corresponding coefficients for the each m_1 calibration together with those from the $(b - y)$ calibration are provided in Table 3.1.

This type of calibration of the m_1 index is not unreasonable. For comparison, HBS proposed that a separate calibration is necessary for some of the coolest dwarfs in their sample, particularly for the $(B - V)$ colors. They chose to meld their two calibrations at a temperature corresponding to a 5000 K dwarf. For the m_1 dwarf calibrations presented here, a temperature of 5500 K is chosen as the intersection point. In addition, their cool dwarf calibration is a linear relation and based on only three field stars with near solar metallicities, whereas the present calibrations are based on a larger sample of cool dwarfs covering a much wider metallicity range from $[\text{Fe}/\text{H}] \approx -3.0$ to $+0.3$.

Figure 3.3: Similar to Figure 3.2 except for the m_1 index. The dashed line again represents the one-to-one relation between the synthetic and observed m_1 colors. The fit required to correct the colors is not plotted because the dwarfs stars appear to follow a different relation than the giants.

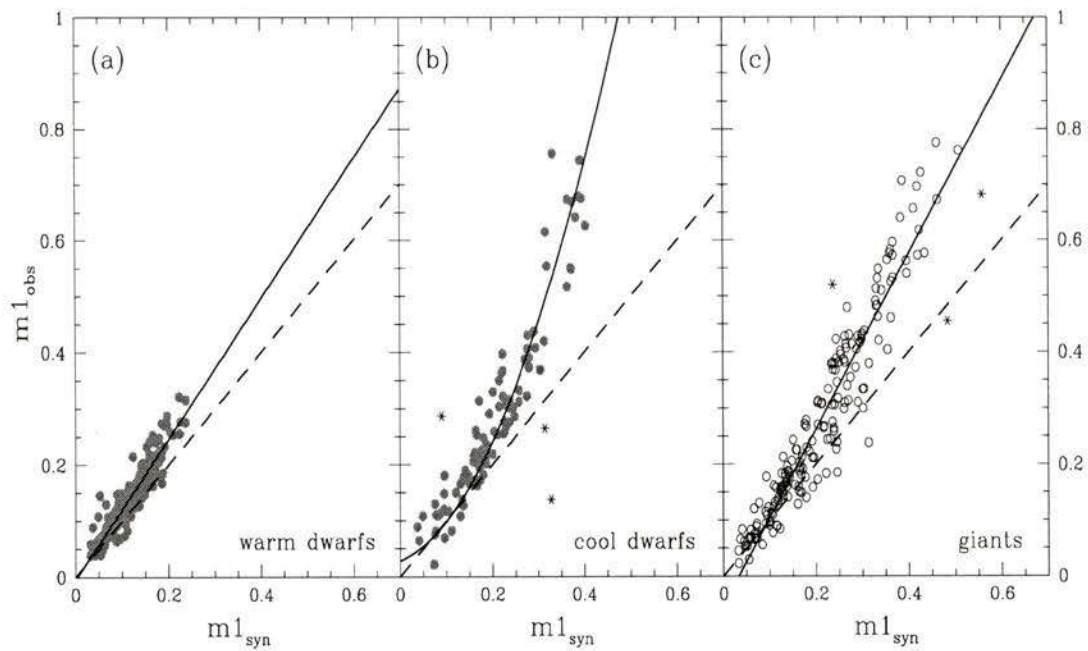

Figure 3.4: Similar to the previous figure except the field stars have been divided into different temperature and gravity regimes in an effort to illustrate the need for separate calibrations. The specifics of how the stars are classified are given in the text. In all panels the solid line represents the color calibrations derived from fits to the data while the dashed line again shows the one-to-one relations for reference. The fits in panels (a) and (c) indicate that a least-squares relation is sufficient to correct the colors for the warm dwarf stars and giants, respectively. However, the cooler dwarfs in panel (b) appear best fit by a second-order polynomial.

Table 3.1: Regression coefficients for calibrations between synthetic and observed color. The colors calibrations are based on the synthetic color as the independent variable and take the form $y = A + Bx + Cx^2$. The number of stars used to derive each calibration equation, N , as well as the resulting standard deviations are also provided.

Color Index	A	B	C	N	σ
$(b - y)$:					
dwarfs & giants	0.011	1.001		536	0.039
m_1 :					
cool dwarfs	0.028	0.346	3.573	97	0.053
giants	-0.052	1.568		178	0.054
warm dwarfs	-0.005	1.253		275	0.020

3.1.3 The c_1 index

From inspection of Figure 3.5, it would appear the Strömgen c_1 index poses even more of a problem to calibrate than the aforementioned m_1 index. While the dwarf field stars are fairly well defined in the plot, they indicate that a high order calibration would likely fit the trend better at lower c_1 values. However, the giants show a significant scatter and do not seem to follow any specific trend. The cause for this extreme discrepancy could lie in the Strömgen u filter which comprises the c_1 index [recall $c_1 = (u - v) - (v - b)$; see Chapter 1]. For example, in late-type field stars (specifically late-G through M types) the flux through the u filter is no longer dominated by the Balmer discontinuity, but rather by a large number of stellar absorption lines which begin to appear at cooler temperatures. Therefore, the c_1 index could suffer from the same flux problems as the m_1 index due to the inability of the synthetic models to fully account for the absorption. Furthermore, the inability of stellar flux models to fit the observed ultraviolet flux for solar-like stars (the so-called “missing UV opacity problem”) could result in problems deriving the c_1 colors from the synthetic spectra. In a recent study of the UV problem, Bell, Balachandran, & Bautista (2001) suggest that the bound-free transitions in Fe I is the main suspect

as an additional absorption source in the wavelength range of 2000-4000Å. However, this opacity source does not pose a significant problem for stellar models of hotter stars due to the greater ionization of Fe I. Nor should it be a problem for models with sub-solar metallicities because of the decreased abundances of iron. In light of this evidence, it would seem that the c_1 colors derived from synthetic spectra of cool, solar-type stars would be in error the most. To complicate matters further, Grundahl et al. (2000b) cite evidence of significant scatter in the c_1 colors of globular cluster giant stars due to variations in carbon and nitrogen abundances. The most likely candidate for causing such variations is the ultraviolet NH molecular band at 3360Å. Therefore, since the synthetic c_1 colors presented here are derived from models with scaled-solar C and N abundances, it is unlikely they would be able to adequately reproduce the observed colors of field stars with anomalous abundances of these elements.

Given the uncertainties inherent to the synthetic c_1 colors, possibly due to the aforementioned evidence as well as the obvious lack of agreement between the synthetic and observed indices in Figure 3.5, it would seem to be difficult to derive a set of color calibrations that would adequately correct the c_1 colors. In an effort to clarify this problem, it is worthwhile to investigate if the problems lie solely in the c_1 colors or in one of its component colors (i.e. the $(u - v)$ or the $(v - b)$ indices). Sections 3.1.1 and 3.1.2 illustrated how different first- and second- order fits are needed to calibrate the synthetic $(b - y)$ and m_1 colors. Based on the fact that m_1 is comprised of two other color indices, namely $(b - y)$ and $(v - b)$, would the $(u - v)$ colors be significantly in error if the $(v - b)$ and $(b - y)$ indices are correctly calibrated? Figure 3.6 presents two plots of the observed versus synthetic $(u - v)$ colors for the field stars using the fact that $(u - v) = c_1 + m_1 + (b - y)$. However, the two panels differ from each other in the fact that the synthetic $(u - v)$ colors in panel (a) are derived using the uncalibrated m_1 and $(b - y)$ indices and those in panel (b) make use of the *calibrated* m_1 and $(b - y)$ colors. The trend in the right-hand panel of Figure 3.6 appears to indicate that the majority of disagreement in panel (a) is nearly removed

Figure 3.5: Similar to Figures 3.2 and 3.3 except for the c_1 index.

Figure 3.6: Plots of the synthetic versus observed $(u - v)$ colors for the field stars. Panel (a) gives the results when the uncalibrated m_1 and $(b - y)$ colors are used to derive $(u - v)$ [using $(u - v) = c_1 + m_1 + (b - y)$], whereas panel (b) uses the calibrated m_1 and $(b - y)$ colors. Dwarf stars are again represented by filled circles and giants by open circles. The disagreement for the synthetic colors in the left-hand panel is largely removed when the calibrated m_1 and $(b - y)$ colors are used to determine $(u - v)$ in panel (b). The solid line in the right-hand panel gives the resulting linear fit derived from the data while the dashed lines again represents the equality between synthetic and observed colors.

when using the calibrated m_1 and $(b - y)$ colors. While the coolest giants appear to deviate slightly from a linear fit, applying a least-squares fit to the entire data set (both dwarfs and giants) yields a slope of 1.009 ± 0.012 and intercept of 0.047 ± 0.012 with $\sigma = 0.082$. Therefore, apart from a zero-point offset between the synthetic and observed $(u - v)$ colors, the discrepancies in c_1 seem to lie predominantly in the synthetic $(v - b)$ indices.

3.2 Accuracy of the Calibrated *uvby* Colors

As mentioned at the beginning of this chapter, one way of testing the accuracy of the corrected Strömgren colors is to transform a theoretical temperature-luminosity isochrone to the observational color-magnitude plane and compare it with photometric data for a cluster of stars. While Figure 3.1 presented the resulting fits to the CMD of M 67 using the uncalibrated colors to transform the isochrone, Figure 3.7 gives the revised fits using the newly calibrated synthetic *uvby* colors. In both panels of this figure, the uncalibrated isochrone is shown as a dotted line while the calibrated isochrones are represented by a solid curve. Overall, the isochrone fits to the CMDs using the calibrated colors in Figure 3.7 are substantially improved compared with those using the uncalibrated indices. The fit to the $(b - y)$ plane in panel (a) indeed shows that a small zero-point correction to the colors was all that was needed to correct the synthetic $(b - y)$ index. However, the $(v - b)$ colors in panel (b) required three different calibrations (see § 3.1.2), both linear and non-linear, to place the synthetic colors onto the observed system. Despite this fact, the calibrated colors appear to correctly reproduce the CMD for M 67 on this color plane.

From the comparisons of the new, 4 Gyr, solar-metallicity isochrone with the CMDs of M 67 in Figure 3.7, the calibrated Strömgren colors appear to be appropriate for field and cluster stars with near solar metallicities. While the field star sample covers a wide range in metallicity, there is no evidence from their photometry that the synthetic color calibrations depend upon chemical composition. Therefore, one should expect the same good agreement between the isochrones and the CMDs of globular clusters with sub-solar metallicities provided reasonable values for the cluster distance, reddening, and age are chosen. This examination and discussion of isochrone fits to a number of metal deficient globular clusters is reserved until the next chapter, while the present discussion will proceed with testing these newly calibrated colors against the field stars used to derive them.

Figure 3.7: Similar to Figure 3.1 except the solid lines now indicate the 4 Gyr isochrone fits using the calibrated colors while the dotted lines are the uncalibrated isochrones. In each panel the color shifts needed to provide the best fits to the data are indicated by $\delta(b-y)$, $\delta(v-b)$, and $\delta(u-v)$.

3.2.1 Testing the Calibrated Colors Using the Field Star Sample

The large number of field stars listed in Table A.1 used to place the synthetic colors onto the observational system also provide an ideal photometric sample to test the resulting calibrated colors due to their broad coverage in T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$. To begin this examination, Figure 3.8 plots various *uvby* CMDs of the field stars from Table A.1 which have $\log g \leq 3.5$ and near solar metallicities ($-0.20 \leq [\text{Fe}/\text{H}] \leq +0.12$). Absolute magnitudes are derived using the star's apparent visual magnitude V along with its corresponding *Hipparcos* parallax. In addition, the stellar colors are corrected for reddening using the $E(b-y)$ values listed in A.1. Superimposed on the observations are two zero age main sequence (ZAMS) models (VandenBerg, private communication) having $[\text{Fe}/\text{H}] = -0.20$ and $+0.12$ transformed to the indicated color-magnitude planes using the newly calibrated Strömgren colors. For the sake of clarity, the sequence of stars encompassed by the two ZAMS loci in the left-hand panel of the figure are represented by filled circles in panels (b) and (c) while all others are shown as asterisks. The resulting fits show that a large number of stars define a tight sequence which lie consistently between the two ZAMS models in all the color planes while the number of the remaining stars lying above the $[\text{Fe}/\text{H}] = +0.12$ ZAMS are most likely evolved turnoff stars and sub-giants. From this type of plot one can see that the same stars are confined between the two ZAMS models in each panel to within reasonable uncertainties in their photometry and absolute magnitudes. This result lends good support to the accuracy of both the calibrated *uvby* colors as well as the bolometric corrections for models with near-solar metallicities.

Figure 3.9 presents two color-color plots of the same set of stars which are located between the two ZAMS in the previous figure. Panels (a) and (b) now plot $(b-y)_o$ versus the dereddened m_o and c_o indices for the solar metallicity dwarfs, respectively, with the majority of stars still lying between the same two ZAMS models in each

Figure 3.8: Fits of two ZAMS models corresponding to metallicities of $[Fe/H] = +0.12$ and -0.20 to the $uvby$ CMDs of all solar metallicity dwarf stars taken from the field star sample. The stars confined between the ZAMS in panel (a) are represented by solid circles in panels (b) and (c).

Figure 3.9: Color-color diagrams of stars confined between the same two ZAMS models from the previous figure.

case. Furthermore, the two calibrated ZAMS also do an excellent job of reproducing the general trend of the field stars over the entire color range plotted, thus lending even more support to the validity of the calibrated colors.

Finally, Figure 3.10 presents a color-temperature and a color-color plot for the field dwarfs that have been divided into separate metallicity bins as indicated by the different symbols. The three ZAMS models overplotted as solid lines are calculated for metallicities of $[\text{Fe}/\text{H}] = -2.0, -1.0, 0.0$. These figures serve to illustrate not only the accuracy of the calibrated colors in transforming the various ZAMS models, but also the importance of the Strömgen m_1 index as a metallicity indicator. While the number of stars in the sample decreases for lower $[\text{Fe}/\text{H}]$ values, all three trends appear to run almost parallel to each other with the higher metallicity stars displaced to larger m_1 values. The figure is extremely helpful in deriving an estimate of star's metallicity based solely on its position in either or both of these diagrams. While panel (a) would require prior knowledge of a star's effective temperature to obtain an

Figure 3.10: The locations of field dwarf stars in the $[T_{\text{eff}}, m_o]$ and $[(b - y)_o, m_o]$ planes according to their metallicities. The different symbols identify the indicated metallicity bins into which the field stars have been grouped. Solid lines represent the ZAMS models transformed using the calibrated Strömgen colors for $[\text{Fe}/\text{H}]$ values of 0.0, -1.0 , and -2.0 .

$[\text{Fe}/\text{H}]$ estimate, panel (b) is an entirely observational and the stars appear to define a tighter sequence.

3.2.2 Testing the Calibrated Colors Using Population II Subdwarf Standards

Extending these types of comparisons and tests to lower metallicities is somewhat more problematic owing to the fewer number of cool, metal-poor stars in the sample which could be used to probe the accuracy of the colors towards the redder limits of the main sequence and giant branch. To remedy this problem, a sample of metal-deficient, Population II field subdwarfs is selected from Table A.1 which have been

extensively studied in the literature. The goal of this process is to investigate if the calibrated *uvby* colors can correctly reproduce the observed Strömgren indices for these Population II stars provided accurate and consistent estimates of their effective temperature, surface gravity, and metallicity are available.

Given that the effective temperature is the most critical determinate of stellar color, Table 3.2 presents a comparison between the temperatures derived in a number of different studies for the sample of Population II subdwarfs considered here. Listed in the first column are the same IRFM temperatures from AAM96 which were adopted to calibrate the synthetic colors. The temperatures quoted by Gratton et al. (1996) and Clementini et al. (1999) were all calculated using an iterative procedure which attempts to fit the flux distribution of an ATLAS9 model atmosphere to the observed spectrum for a particular star (see § 3 of Gratton et al. 1996 for specifics). Effective temperatures from the Gratton et al. (2000) study were calculated from dereddened $(B - V)_o$ and $(b - y)_o$ colors using the color- T_{eff} transformations from Kurucz (1993). Finally, Axer et al. (1994) chose to calculate T_{eff} spectroscopically by fitting the profile wings of the first four Hydrogen Balmer lines.

While all of these studies rely on different methods of deriving T_{eff} , they appear to yield quite consistent results. In general, most of the effective temperatures derived from the IRFM by AAM96 show good agreement with those determined from the indicated sources to within ± 100 K. The most notable case of agreement is HD 19445 for which the estimates from the five different sources yield a mean T_{eff} of 6055 K with a deviation of only ± 14 K. There are, however, a few cases where the agreement is not as satisfactory. For instance, the IRFM temperatures for HD 134439 and HD 134440 are both ≈ 100 -150 K cooler than those derived in other studies. While it is not immediately apparent why the temperatures estimates for these two stars are in slight disagreement, the Strömgren colors derived from models using the higher temperatures appear in better agreement with the actual photometry (see below).

In order to derive the synthetic Strömgren colors for these subdwarfs, accurate

estimates of a star's surface gravity and metallicity must supplement the effective temperature. The majority of $\log g$ estimates for this subdwarf sample were taken from the study of Nissen, Høg, & Schuster (1997) while $[\text{Fe}/\text{H}]$, absolute magnitude, dereddened broadband color, and reddening values were obtained from Carretta et al. (2000). Table 3.3 presents these adopted parameters together with their dereddened photometry for the selected sample of subdwarfs.

Table 3.3: Fundamental parameters and *uvby* photometry for selected Population II subdwarfs. Estimates for $\log g$ are taken from Nissen, Høg, & Schuster (1997) while $[\text{Fe}/\text{H}]$, absolute magnitude, broadband color, and reddening values are obtained from Carretta et al. (2000) unless otherwise noted. The Strömgren reddening value has been derived assuming $E(b - y) = 0.734E(B - V)$.

Table 3.4 lists the results of a number of calculations that have been carried out in an attempt to match the observed, dereddened colors of the subdwarf sample. While the Strömgren color indices for each star have been derived from the calibrated *uvby* colors, the $(B - V)$ colors are calculated from the broadband C-T relations of Vandenberg (2001, in preparation). The first set of model colors uses the stellar parameters adopted by the AAM96 investigation while the second set considers the same IRFM temperature but with the surface gravity and metallicity estimates listed in Table 3.3. For the majority of stars the best agreement between the predicted and observed color indices occurs for the second set of calculations. However, a few stars still appear to show some differences, particularly in the m_o and c_o colors, regardless of which set of parameters is adopted. Possible reasons for such discrepancies are discussed on a star by star basis below.

Table 3.4: The *uvby* (and *BV*) colors derived from the calibrated Strömgen colors assuming various models adopting the indicated values of T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ for the sample of Population II subdwarfs.

- *HD 140283*: This well documented sub-giant is the most metal-deficient star in the subdwarf sample. The third model for HD 140283 listed in Table 3.4 considers the T_{eff} obtained from the Axer et al. (1994) study. It seems clear this particular model yields much better agreement for all indices due to the adoption of a higher temperature than what is predicted by the IRFM. Indeed, Ryan, Norris, & Beers (1999) have pointed out that the IRFM temperatures derived by AAM96 appear to show nonphysical trends at very low metallicities (i.e. $[\text{Fe}/\text{H}] < -2.0$), which could cast some doubt on temperatures derived for stars with extremely low abundances. Furthermore, recent investigations by Fuhmann (1998) and Grundahl et al. (2000a) advocates adopting a slightly higher temperature of ≈ 5800 K for HD 140283 due to the effects of reddening in the determination of T_{eff} .

While this may solve the problem for HD 140283, the question arises concerning the validity of the color calibrations used to correct the synthetic Strömgren colors. If the derived IRFM temperatures are systematically in error by a few hundred Kelvin for extremely metal-deficient field stars, this could in turn affect the size of the correction needed to put the model colors onto the observed system. However, the number of stars (particularly dwarfs) with $[\text{Fe}/\text{H}] < -2.0$ listed in Table A.1 totals just over 35 which is only a small fraction of the total sample on which the color calibrations are derived. Therefore, it seems unlikely that any possible errors in the IRFM temperatures could pose problems for the low metallicity synthetic colors.

- *HD 25329*: This cool subdwarf shows that largest discrepancy between the calculated and observed Strömgren indices, particularly for m_o which differs by more than 0.1 mag. It seems quite unlikely that errors in the adopted T_{eff} could be causing such mismatch given the good agreement between the $(b - y)$ and $(B - V)$ colors. In addition to the temperatures listed in Table 3.2,

Thévenin & Idiart (1999) and Taylor (1994) derive temperatures of 4846 K and 4893 K, respectively, for HD 25329 leading to an average T_{eff} of 4854 ± 20 K. Ruling out possible errors in temperature, it also seems improbable this star could have a surface gravity or metallicity which deviates significantly from the values used for this study. Moreover, even if the reddening is significantly larger than the $E(b - y) = 0.0$ adopted here, it would only serve to increase the observed value for m_o [since $m_o = m_1 + 0.347E(b - y)$]. To shed some light on this problem, Speisman (1992) comments that HD 25329 exhibits unusually strong CN absorption for a metal-poor subdwarf, and the abundance analysis of Carbon et al. (1987) yields $[C/Fe] = +0.44$ and $[N/Fe] = +0.45$. In addition, Meléndez & Barbuy (2001) report a slightly higher oxygen abundance than usually found in Population II field stars ($[O/Fe] = +0.48$). Recent papers have investigated the effect of enhancements in the CNO process elements on both the m_1 and c_1 index due to increased absorption by the CN and NH molecular bands at 4215\AA and 3360\AA , respectively (e.g., see Briley, Grundahl, & Anderson 1999, Grundahl et al. 2000, and Hilker 2000). Therefore, it seems reasonable to expect some disagreement between the observed and calculated m_o and c_o colors due to the unusually high abundances of C, N, and O in HD 25329. Since the synthetic colors derived in this work are all derived assuming scaled solar carbon and nitrogen abundances, the enhancement in CNO would affect both the line and continuum absorption due to the treatment of OH and CH bound-free absorption in the synthetic spectra calculations. To investigate the effects of such elemental enhancements on the Strömgen colors, a new model atmosphere and synthetic spectrum for HD 25329 is constructed assuming the same parameters as before (4842/4.75/-1.69) but with the abundances for C, N, and O enhanced by +0.44, +0.45, and +0.48, respectively. The resulting colors are derived using the methods described in the last chapter and calibrated using the relations listed in Table 3.1. From the results of this new model listed in

Table 3.4 there appears to be an increase in the model m_o colors by about 0.06 mag. While this increase is still not sufficient to match the observed m_o colors of HD 25329, it does serve to illustrate the effect of CNO enhancements on the Strömgen m_1 index.

- *HD 134439/134440*: These two neighboring stars are among the coolest subdwarfs in the sample. It appears from the model calculations that the $(b - y)$ colors are the most discrepant in both HD 134439 and 134440 if the IRFM temperatures of AAM96 are adopted. However, the comparisons given in Table 3.2 show these effective temperatures appear to be ≈ 130 K cooler than those of Gratton et al. (2000) and Clementini et al. (1999) for both stars. Furthermore, Prieto & Lambert (2000) quote a temperature of 5110 K for HD 134439, while Nissen, Høg, & Schuster (1997) give 5040 K and 4842 K for 134439 and 134440, respectively. Under these considerations, an additional model is given for both stars in Table 3.4 which adopts the T_{eff} estimates of Clementini et al. (1999). While the better agreement in the $(b - y)$ colors (and arguably $B - V$) appears to favor the higher temperatures for the subdwarf pair, the m_o colors are now mismatched. One possible explanation to this problem is that HD 134439/134440 are suffering from the same anomalous CNO abundances as HD 25329. However, a more likely explanation lies in the fact that both of these stars exhibit a near-solar abundance of the α process elements ($[\alpha/\text{Fe}] = 0.0$) as opposed to $[\alpha/\text{Fe}] = +0.3$ commonly found in most metal-poor subdwarfs. Indeed, King (1997) derived elemental abundances from high resolution and high S/N spectra for these two stars and discovered the pair exhibit little or no significant enhancement of the α elements ($[\alpha/\text{Fe}] \approx 0.0$). In addition, Fulbright (2000) also confirms the pair has near-solar $[\alpha/\text{Fe}]$ values. Given these facts, it is difficult to assess how the indices derived in Table 3.4 from the calibrated Strömgen colors would differ given an under-abundance of the α process ele-

ments. As mentioned in Chapter 2, the lowest metallicity synthetic colors were initially calculated assuming $[\alpha/\text{Fe}] = +0.3$. Therefore, two additional models are computed for HD 134439/134440 assuming the same T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ but with $[\alpha/\text{Fe}] = 0.0$. These two new models show that adoption of $[\alpha/\text{Fe}] = 0.0$ does increase the calculated m_o colors and brings them into better agreement with the observed indices for each star. However, the fact that model m_o colors are still ≈ 0.02 mag too low or that the c_o colors now show a slightly worse agreement than before cannot be readily explained.

- *HD 64090, HD 103095, and HD 188510*: According to the models listed in Table 3.4, the only disagreement between the synthetic and observed colors for these stars lies in the c_o index. As was the case with HD 25329, a possible explanation is that these subdwarfs could have abundances for C, N, and/or O which differ significantly from other field dwarfs. Unlike HD 25329, however, the analysis of Carbon et al. (1987) reveals that all of these stars exhibit an *under*-abundance of nitrogen with respect to most other field subdwarfs ($[\text{N}/\text{Fe}] = -0.3, -1.0,$ and -0.7 for HD 64090, 103095, and 188510, respectively). From the previous discussion, lower nitrogen abundances would imply *less* absorption in the Strömgen u filter from the NH band at 3360 \AA , leading to a *lower* value for the c_1 index than what is predicted by the models. However, it is not clear why such an under-abundance of nitrogen does not appear to change the m_o colors significantly due to the effects of the CN band in the v filter.

In conclusion, the calibrated *uvby* colors appear to provide a satisfactory match to the observed indices for most of the selected subdwarfs. Although a few of the stars exhibit some abundance anomalies which lead to a mismatch with the calculated colors, these problematic stars also serve to illustrate the obvious usefulness of the Strömgen m_1 and c_1 indices as indicators of abundance variations in cool stellar atmospheres. Note, however, that the explanations given above for the discrepancies

in the calculated/observed subdwarf colors are only suggestive. It is quite possible that errors in the photometry, the calibrated colors, the reddening estimates, and/or the basic stellar parameters are at the root of the problem, despite the fact these subdwarfs have been extensively studied.

3.2.3 Comparisons with Other Strömgren Color-Temperature Relations

The final section in this chapter investigates how the newly calibrated Strömgren colors compare against other *uvby* C-T relations available in the literature. For this purpose a number of color transformations are selected which have been derived both theoretically and empirically. While both methods have their advantages and disadvantages as discussed in Chapter 1, it is interesting to see how past C-T relations compare to the current set of colors which are calculated from synthetic models and calibrated against stars that have empirically determined parameters.

Figures 3.11 and 3.12 compare the newly calibrated *uvby* C-T relations against the previous MARCS-SSG results of Vandenberg & Bell (1985, hereafter VB85) and the latest grid of ATLAS9 model colors computed and discussed by Castelli et al. (1997, hereafter C97) for two representative $[\text{Fe}/\text{H}]$ values. In each panel $\log g$ is plotted versus the indicated color and solid lines are used to represent the isotherms corresponding to the newly calibrated colors while the uncalibrated colors are shown as dotted lines. In addition, the overplotted filled circles give the C97 colors whereas open circles represent the VB85 data. Differences between the current non-calibrated colors and the VB85 colors can be attributed to improvements in the MARCS-SSG synthetic models over the years, while differences compared to the C97 colors are likely due to different treatments of the line blanketing and the use of two separate modeling programs in generating the synthetic Strömgren colors (ATLAS9 and MARCS-SSG).

At first glance, it is difficult to distinguish the differences between the VB85

Figure 3.11: A comparison of various theoretical $(b - y)$ and $(v - b)$ C-T relations for $[\text{Fe}/\text{H}] = -1.5$. In both panels the calibrated colors are represented by solid lines while the uncalibrated colors are given by dotted lines. Overplotted in each panel are the colors based on the Kurucz ATLAS9 models (filled circles) computed by Castelli et al. (1997) and the previous MARCS-SSG colors (open circles) of VandenBerg & Bell (1985).

Figure 3.12: Same as the previous figure except for $[Fe/H] = 0.0$.

and non-calibrated colors for the lower metallicity case in Figure 3.11. It appears the agreement between the two is quite good for the $(b - y)$ colors, and arguably as good in the $(v - b)$ plane with the exception of the 4500 K isotherm for which the VB85 colors are slightly too blue. However, the same agreement does not hold true for the solar metallicity (Figure 3.12) C-T relations. While the correspondence is good for warmer temperatures (i.e. $T_{\text{eff}} > 5500$ K), it appears the VB85 colors are systematically too blue compared to the uncalibrated colors. These discrepancies are likely due to the advancements in the stellar synthesis models, such as the inclusion of more detailed atomic and molecular line lists as well as improved low temperature opacities since the VB85 colors were calculated.

For the ATLAS9 colors, the differences between the $(b - y)$ C-T sets appear to be mainly a zero-point offset, likely due to the adoption of slightly different Vega-based normalizations for the synthetic indices. The $(v - b)$ colors are a little more difficult to explain given that the cooler ATLAS9 isotherms are systematically redder for $T_{\text{eff}} < 6000$ K (in addition to an apparent zero-point difference) than the uncalibrated colors. In fact, the ATLAS9 $(v - b)$ colors appear to be more consistent with the current set of *calibrated* colors for cooler temperatures. This may be due to the ATLAS9 line lists being more detailed than those used in the SSG code. Despite this, the ATLAS9 colors are still too blue to equate with the newly calibrated colors and would not likely be able to accurately reproduce the colors of the field stars with cooler effective temperatures.

To further exemplify the comparison between the different theoretical *uvby* colors discussed so far, Figures 3.13 and 3.14 plot a 10 Gyr isochrone transformed to two Strömgen color-magnitude planes using both the current C-T relations (calibrated and uncalibrated) as well as those derived from the ATLAS9 models. It is important to note that the same bolometric corrections (namely those of Wood & Bessell) have been used to derive M_V in each plot. This ensures that any difference between the isochrones is due solely to variations in the color transformations. Also, the VB85

Figure 3.13: Comparisons of a 10 Gyr, $[\text{Fe}/\text{H}] = -1.5$ isochrone transformed to the indicated Strömgren color planes using the calibrated, uncalibrated, and ATLAS9 model colors.

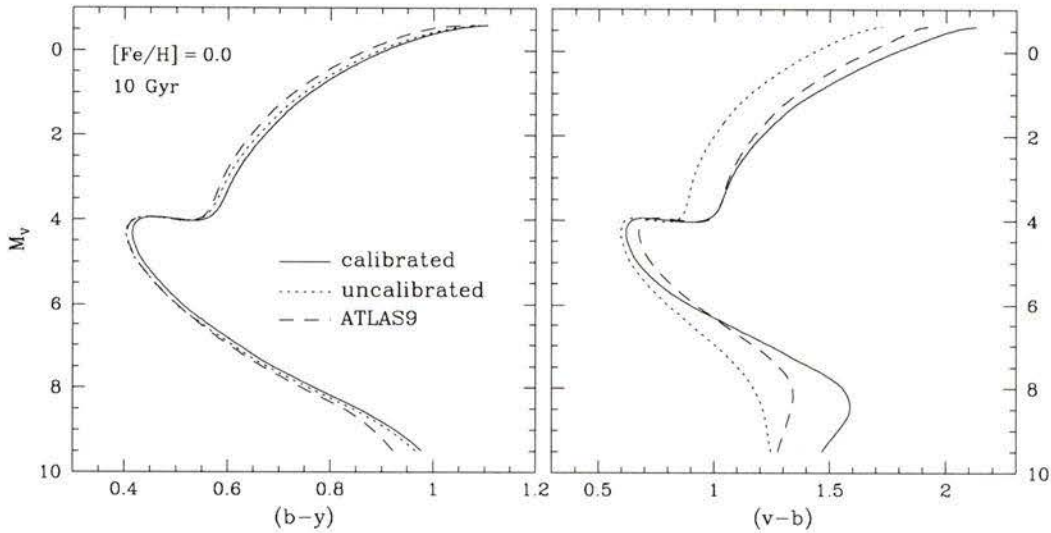

Figure 3.14: Same as previous figure except for a 10 Gyr isochrone with $[\text{Fe}/\text{H}] = 0.0$.

colors were not used for this comparison due to their limited coverage of parameter space. From these two figures, one can see that the differences in the C-T relations have quite large effects on the location and morphology of the isochrones, especially in the $[(v - b), M_V]$ plane. It is encouraging, however, that the $(b - y)$ isochrones for each metallicity case appear to follow roughly the same trend from the main sequence through the giant branch with only small color differences between them. As mentioned earlier, these color shifts are likely due to different zero-point standardizations between the ATLAS9 and calibrated MARCS-SSG C-T grids. While it does appear the ATLAS9 isochrones would better agree with the calibrated isochrone near the turnoff region if a negative color shift were applied, they are consistently too blue to match the calibrated model for the coolest temperatures.

Turning to comparisons involving empirically derived C-T relations, a number of recent calibrations of T_{eff} versus $(b - y)$ have been extracted from the literature which are briefly described in the following:

- Saxner & Hammerbäck (1985, hereafter SH85) presented one of the first empirical calibrations of T_{eff} versus $(b - y)$ based on stellar temperatures derived using the IR flux method of Blackwell & Shallis (1977). Their examination was based on a total of 30 main sequence stars ranging in temperature between 5800 and 7000 K whose colors fall within the range of $0.20 < (b - y) < 0.40$. While the stars used in their study covered a limited range in metallicity, an abundance term is included in the final calibration to account for possible metallicity variations.
- The IRFM temperatures for ≈ 75 stars (dwarfs and giants) used in the Gratton et al. (1996, hereafter GCC96) calibration were collected from the lists of Bell & Gustafsson (1989) and corrected to the same temperature scale as Blackwell & Lynas-Gray (1994). This large sample of stars covered a much wider range in both temperature and gravity than the aforementioned SH85 study, and their final dwarf calibration can be reasonably applied to stars with $(b - y)$ colors

between 0.06 and 0.79.

- The $(b - y)$ - T_{eff} calibration of Alonso et al. (1996b, hereafter AAM96b) makes use of the same IRFM temperatures used to calibrate the synthetic *uvby* colors at the beginning of this chapter. The sample of approximately 500 stars is by far the largest with well-determined temperatures to date and includes dwarfs and subgiants with spectral types F0 to K5 covering a wide range in metal content ($+0.5 \leq [\text{Fe}/\text{H}] \leq -3.0$). To account for the effects of differing metal abundances and gravity in their sample stars, the final temperature calibrations are a function of not only $(b - y)$, but also $[\text{Fe}/\text{H}]$ and c_1 .

Figure 3.15 compares the empirical T_{eff} - $(b - y)$ calibrations derived in the various studies mentioned above together with the relationship between $(b - y)$ and T_{eff} predicted by the calibrated Strömgren colors for a representative $\log g = 4.5$ appropriate for main sequence dwarf stars. For those calibrations which include a metallicity term (SH85 and AAM96b), all of the curves plotted in the figure assume a solar metallicity ($[\text{Fe}/\text{H}] = 0.0$). Also, the original calibration of SH85 has been extended from its original calibration limit of $(b - y) = 0.45$ to $(b - y) = 0.6$ to illustrate its limited validity for cooler temperatures. It is quite reassuring that all three empirical calibrations appear to agree well in the range $0.2 < (b - y) < 0.5$ which illustrates the consistency of the IRFM in predicting stellar temperatures. In addition, their correspondence with the C-T relations derived from the calibrated colors serves to prove that the synthetic Strömgren colors can accurately relate stellar color and temperature for $(b - y)$. Indeed, the calibrated C-T relation together with the calibrations of GCC96 and AAM96b are in superb agreement over a broad temperature and color range. To further illustrate this point, a solar color of $(b - y) = 0.412$ has been derived from the calibrated colors assuming $T_{\text{eff}} = 5770$, $\log g = 4.44$, and $[\text{Fe}/\text{H}] = 0.0$. Applying the same solar temperature to the relations of SH85, GCC96, and AAM96b yields $(b - y)_{\odot} = 0.407$, 0.401, and 0.414, respectively.

Figure 3.15: A comparison of empirical C-T calibrations from the indicated studies with the relationship between $(b-y)$ and T_{eff} predicted by the calibrated Strömgen colors for $\log g = 4.5$.

In summary, this chapter has discussed the derivation of the color calibrations needed to put the synthetic *uvby* colors onto the observational systems. Furthermore, the accuracy of newly calibrated colors was put to the test by comparing them with both a large sample of field stars, as well as a selected group of well-observed Population II subdwarfs. While the tests attempt to cover a number of observational regimes with stars that define a wide range in effective temperature, gravity, and metallicity, there are still a number of areas in which the calibrated colors remain untested. For instance, no mention was made as to the validity of the colors for more metal-poor giant stars for two reasons. First, very few metal-poor field giants have been as extensively studied as the dwarf and subdwarf sample presented here. Second, and more importantly, the effects of CN variations seen in a few subdwarfs are more common and profound among RGB stars in globular clusters (Grundahl et al. 2000b) and in the field (Hilker 2000) due to evolutionary effects. Therefore, deriving an adequate sample of metal deficient giants to test the colors against would require some prior knowledge of their chemical abundances (particularly carbon and nitrogen) in order to yield accurate results. Rather than resort to this type of analysis, the next chapter will continue to test the calibrated colors by comparing model isochrones to the CMDs of a number of metal-poor globular clusters and metal-rich open clusters. These clusters serve as perfect laboratories against which to test the Strömgren indices since all of the member stars have the same distances, reddenings, ages, and metallicities. Thus, errors due to star-to-star differences in these properties, which were inherent with the field stars, are reduced to a minimum with cluster stars. In addition, the next chapter will compare the isochrone fits to cluster CMDs in the Strömgren system with those in the broadband *UBVRI* system in order to check the consistency of the models in two different photometric systems.

Chapter 4

Examining Star Clusters With Strömgren Photometry

Star clusters serve as ideal testing grounds in which to study the theories of stellar structure and evolution because their members are believed to have all formed at approximately the same time from the same molecular cloud. As a result, individual clusters have essentially the same age, distance, and chemical composition. These stellar populations can provide valuable insight into the structure and evolution of the galaxy as a whole. For instance, a simple correlation between cluster ages, metallicities, velocities, and spatial locations leads to the conclusion that the galaxy is composed of two distinct stellar populations. The extremely metal-poor, populous globular clusters (GCs), which are among some of the oldest known objects in the universe, represent one population, while the younger, metal-rich galactic open clusters (OCs) comprise the other.

Within the past two decades a large amount of high quality photometric data for a significant number of GCs and OCs has accumulated in the literature due in part to the use of large format CCD detectors in observations. This type of photometric accuracy has resulted in cluster color-magnitude diagrams (CMDs) which

exhibit an extremely well defined sequence of stars in different stages of evolution ranging from the main sequence (MS) through the red giant branch (RGB). As a result, the technique of isochrone fitting discussed earlier has greatly benefitted from the increased photometric precision by yielding more reliable age estimates for these clusters. Ideally, the best way to determine a cluster's age (once the distance, reddening, and metallicity of the clusters has been constrained in some way) is to assess which isochrone provides the best fit to the CMD in the vicinity of the turnoff (TO). This TO point, defined as the location where stars exhaust their core hydrogen fuel and begin to evolve away from the main sequence, is the most sensitive indicator of cluster age owing to the fact that the older the cluster, the redder and less luminous the TO point. While this method has been widely applied to a large sample of clusters with broadband (*UBVRI*) photometric data (see, e.g., Vandenberg 2000 and Salaris & Weiss 1997 for recent discussions), the interpretation of CMDs in the Strömgren filter system has been rarely discussed in years past due to the fact that accurate *uvby* photometric data is largely unavailable for a sufficient number of star clusters. Moreover, any interpretation of existing cluster photometry using theoretical stellar models has suffered from the lack of modern and precise color-temperature (C-T) relations for the *uvby* system.

This chapter sets forth to remedy these problems and also illustrate the viability of the Strömgren photometric system as an alternative to the broadband system for cluster studies from two fronts. First, the accuracy of the synthetic Strömgren C-T relations calibrated in the previous chapter are further tested by fitting isochrones to the *uvby* CMDs for a selected sample of clusters. Indeed, the reliability of the calibrated *uvby* colors for near-solar abundances has already been demonstrated for the case of the open cluster M 67 (see Figure 3.7). In addition to M 67, the current study makes use of *uvby* data for a number of other OCs and metal-poor GCs to both further constrain the accuracy of the model colors for solar metallicities, as well as to extend the tests to lower abundances. Second, and more importantly, broadband

data for these clusters are collected from the literature to assess whether the same isochrone fits the cluster CMDs independently of the color [i.e. $(b - y)$ or $(B - V)$] that is employed¹.

In the discussion which follows, a few general requirements should be kept in mind when inspecting the isochrone fits to the cluster CMDs. First, for a given cluster, the fits on different Strömgren color planes should be of the same quality. Next, little or no ad hoc color shifts should be necessary to adequately match the data once the appropriate reddening for the cluster is adopted. Finally, estimates for quantities such as age and distance should be totally independent of which color is used for the isochrone fit. Adhering to these basic guidelines not only assures that a “good” isochrone fit to the data has been achieved, but also reinforces the validity of the Strömgren C-T relations used to transform the isochrone.

4.1 Open Clusters

Open clusters serve as excellent tracers of the structure and chemical evolution of the galactic disk due to their wide distribution in age and metallicity. While photometric observations of OCs in the four-color system have received some moderate attention in literature, the amount of high quality *uvby* data currently available is still quite small when compared to broadband observations. For this reason, a recent observing program aimed at obtaining *uvby* photometry for two OCs was performed in conjunction with the present study. Including these recent observations together with data for other OCs in the present sample provides a variety of clusters covering a wide range in age against which the accuracy of the calibrated Strömgren colors can be further tested for metallicities near solar.

¹It should be mentioned that throughout this chapter comparisons involving isochrones fitted to various broadband CMDs are transformed to the observed plane using the semi-empirical C-T relations presented by VandenBerg (2001, in preparation) and briefly described in VandenBerg (2000).

4.1.1 The Hyades

The Hyades is perhaps the most documented open cluster and has served as an important “standard” cluster against which other stellar populations have been compared for many years as well as a fundamental constraint on the extragalactic distance scale. Furthermore, with a well established metallicity of $[\text{Fe}/\text{H}] \approx +0.12$ (Cayrel et al. 1985, Boesgaard 1989, and Boesgaard & Friel 1990) it is the ideal test for stellar models and the synthetic Strömrgren colors for metallicities above solar. In a recent study Perryman et al. (1998) presented the *Hipparcos* view of the Hyades in which they investigated the dynamical properties of the cluster as well as its HR diagram and age. More importantly, however, their examination of the three-dimensional spatial and velocity distribution of member stars lead to a precise estimate of the distance to the Hyades ($D = 46.24 \pm 0.27$ pc). Even more recently de Bruijne, Hoogerwerf, & de Zeeuw (2001, hereafter BHZ) derived secular parallaxes from *Hipparcos* proper motions in order to isolate a set of 88 “high-fidelity” cluster members which define a tight main sequence in the $[(B - V), M_V]$ plane.

The Hyades cluster is one of the few OCs which has received a considerable amount of attention in the Strömrgren system. The extensive survey of Crawford & Perry (1966) reported *uvbyH β* photometry for 132 member stars down to $V \approx 8$ mag. In addition, Eggen (1982) and Reglero et al. (1992) obtained observations for a combined total of 100 stars which extended the cluster data down to $V \approx 11$. Figure 4.1 presents a number of *uvby* CMDs for the Hyades using a total of 67 stars from the “high-fidelity” sample of BHZ which have available Strömrgren photometry. Overplotted in each panel of the figure is a ZAMS model (VandenBerg, private communication) corresponding to the Hyades metallicity of $[\text{Fe}/\text{H}] = +0.12$. Overall, the ZAMS shows exceptional agreement for the majority of stars lying on the main sequence. The few stars showing the largest deviation from the ZAMS with $M_V \leq 3$ are likely slightly evolved. In addition to these CMDs, Figure 4.2 illustrates the accu-

Figure 4.1: Fits of a ZAMS model having a metallicity of $[Fe/H] = +0.12$ to the 67 “high-fidelity” members of the Hyades open cluster. Absolute magnitudes for each star have been derived from the secular parallaxes determined by de Bruijne, Hoogerwerf, & de Zeeuw (2001). No reddening corrections have been applied to the photometric data.

Figure 4.2: Color-color plots of $(b-y)_o$ vs. m_o (a) and $(b-y)_o$ vs. c_o (b) overplotted with the same $[Fe/H] = +0.12$ ZAMS from previous figure.

racy of the calibrated colors in matching the ZAMS to the data on various Strömgren color-color diagrams. Overall, the ZAMS fits in both figures are exceptionally good, and the use of high quality Hyades members from BHZ ensures that only single stars lying on or near the main sequence are considered in the plots (i.e., all binaries and anomalous stars are excluded).

4.1.2 M 67

M 67 has long been an important cluster for calibrating solar metallicity stellar models. Its moderately old age combined with its rather rich population also provides an opportunity to investigate to the evolution of solar like stars near the end of the main sequence phase. Spectral abundance analyses have constrained its metallicity to be just slightly less than solar ($[Fe/H] = -0.04$; Montgomery, Marschall, & Janes 1993). In the last chapter the accuracy of the calibrated Strömgren colors were illustrated by fitting a 4 Gyr isochrone with $[Fe/H] = -0.04$ to the *uvby* CMDs of M 67.

Assuming a distance modulus of $(m - M)_V = 9.60$ and a reddening of $E(b - y) = 0.029$ (Schlegel et al. 1998), it appears from Figure 4.3 that the isochrone matches the data quite well for all colors. In addition, identical fits using the same isochrone are obtained for the BV and VI data from Montgomery et al. (1993) in Figure 4.4.

4.1.3 NGC 6819 and NGC 188

In an effort to increase the amount of Strömgren data available for star clusters, observations of the two prominent open clusters NGC 188 and NGC 6819 were obtained by the author in the $uvby$ system. Both of these OCs together with their counterpart M 67 serve as ideal clusters in which to test the calibrated $uvby$ colors for solar metallicities due to their range in ages but very similar chemical compositions. The details of the observation process and reduction of the photometric data are left to Appendix C while the current discussion will precede with the presentation of the $uvby$ CMDs of NGC 188 and NGC 6819.

Figure 4.5 exhibits various $uvby$ CMDs for NGC 6819 down to $V \approx 19.5$. While the cluster suffers from significant field star contamination in its CMDs, a tight, well-defined main sequence and turnoff as well as a noticeable population of clump giant stars are easily seen despite the clutter. In addition, the preferred isochrone with an age of 2.5 Gyr is overplotted in each panel. As with M 67 and the Hyades, the fits of the isochrone to the CMDs are exceptionally good with little or no color shifts necessary to adequately match the data. The metallicity of NGC 6819 is fairly well constrained with recent estimates hovering around a near solar value. Recent spectroscopic examinations have yielded $[Fe/H] = +0.05 \pm 0.11$ (Friel & Janes 1993) and $+0.09 \pm 0.03$ (Bragaglia et al. 2001). However, it is important to note that the Friel & Janes metal abundance is highly dependent on the cluster's reddening value (which they adopted to be $E(B - V) = 0.280$) due to the use of a photometrically based T_{eff} scale in their analysis. The Bragaglia et al. value, on the other hand, is

Figure 4.3: Fits of a 4 Gyr isochrone for the indicated parameters to the various *uvby* CMDs of M 67: note the isochrones have been shifted in color by the indicated amounts to provide the best match to the photometric data. The *uvby* data has been provided by F. Grundahl.

Figure 4.4: Fits of the same 4 Gyr isochrone from the previous figure to the indicated Strömgren and broadband CMDs. The BV and VI photometric data are taken from Montgomery et al. (1993).

independent of the assumed reddening, and they used their spectra to derive $E(B - V) = 0.140 \pm 0.04$. While other quoted values for the reddening range as low as $E(B - V) = 0.1$ (Kalirai et al. 2001) up to 0.3 (Lindoff 1972), the recent reddening maps of Schlegel et al. (1998) give 0.204. Given this evidence, the NGC 6819 CMDs shown in Figure 4.5 are fit with a solar metallicity isochrone with the photometry being corrected for reddening using a value of $E(B - V) = 0.145$. The adoption of these parameters appears to yield an adequate fit to the data without any significant color shifts being required and gives a cluster age of 2.5 Gyr. Figure 4.6 shows how the fit of the same isochrone on the $[(v - y)_o, M_V]$ CMD compares with the fit to the $(B - V)$ data of Rosvick & Vandenberg (1998). In each panel of this figure, the same isochrone appears to give similar interpretations of the photometric data when identical cluster parameters are assumed.

NGC 188 has been the subject of much study in the past because it is one of the oldest known open clusters. Figure 4.7 presents the Strömgren CMDs for NGC 188

Figure 4.5: Fits of a 2.5 Gyr isochrone for the indicated parameters to the various *uvby* CMDs of NGC 6819.

Figure 4.6: Fits of the same 2.5 Gyr isochrone from the previous figure to the indicated Strömgen and broadband CMDs. The BV photometric data are taken from the study of Rosvick & Vandenberg (1998).

fitted with a 7 Gyr, $[\text{Fe}/\text{H}] = -0.04$ isochrone. The metallicity of the cluster is comparable to that of the aforementioned NGC 6819 and M 67 with modern estimates of $[\text{Fe}/\text{H}] = 0.02 \pm 0.11$ (Caputo et al. 1990), -0.12 ± 0.16 (Hobbs et al 1990), and -0.02 (Twarog & Anthony-Twarog 1989). Furthermore, the fact that NGC 188 is considerably older than the OCs previously discussed is apparent by the smooth distribution of stars at the cluster turnoff and well populated subgiant and red giant branches. Again, the 7 Gyr isochrone appears to match the data quite well on all color-magnitude planes from the MS through the RGB. In a recent work, Sarajedini et al. (1999) published their high-precision $UBVRI$ photometry for NGC 188 and used it to derive the cluster's reddening, distance, and age. Their $[(B - V), M_V]$ CMD is plotted in the right panel of Figure 4.8 as a comparison against the Strömgen equivalent in the left panel. Both CMDs are again fitted with the same 7 Gyr isochrone used in Figure 4.7 assuming the same cluster parameters. A Schlegel et al. reddening of $E(B - V) = 0.087$ has been used to correct both sets of data along with a distance

modulus of $(m - M)_V = 11.40$. These values correspond well with the reddening and distance modulus of 0.09 ± 0.02 and 11.44 ± 0.08 , respectively, determined by Sarajedini et al. from their comparison of the cluster data against the M 67 photometry of Montgomery et al. (1993). Furthermore, their investigation also led to a derived age for NGC 188 of 7.0 ± 0.5 Gyr, in precise agreement with the age suggested from isochrone fits to the *uvby* data presented here.

Figure 4.7: Fits of a 7 Gyr isochrone for the indicated parameters to the various $uvby$ CMDs of NGC 188.

Figure 4.8: Fits of the same 7 Gyr isochrone from the previous figure to the indicated Strömgen and broadband CMDs. The BV photometric data are taken from the study of Sarajedini et al. (1999).

4.2 Globular Clusters

Globular clusters have long been considered to be the oldest known objects in the Milky Way, and for this reason there is a great interest in deriving the absolute ages of these systems in order to constrain the age of both the galaxy and the universe. With the availability of precise and well calibrated photometry mentioned at the beginning of this chapter, the problems of determining accurate GC ages no longer lie in the lack of accurate photometric data, but rather in determining reliable values for the basic parameters which enter into the derivation of a cluster's age, namely its distance, reddening, and metallicity. One common impediment in age determinations lies in establishing an appropriate cluster distance scale. For example, recent studies involving fits of local subdwarfs with accurate *Hipparcos* parallaxes to GC fiducials have favored ages of $\lesssim 12$ Gyr for the oldest clusters (Reid 1997 and Gratton et al. 1997). Ages from RR Lyrae studies, on the other hand, seem to imply ages $\gtrsim 16$ Gyr

(Layden et al. 1996, Fernley et al. 1998, and Gratton 1998). Given the obvious lack of agreement in adopted distance scales and derived ages between various studies, Strömgren photometry can offer a viable alternative to estimating cluster ages by circumventing the distance problem. Recently, Grundahl et al. (2000a) investigated the possibility of deriving a distance-independent age for the globular cluster M 92. While their analysis yielded an intermediate age for ≈ 14.5 Gyr for the cluster based on isochrone fits to the dereddened $[(v - y)_o, c_1]$ diagram, these resulting fits (see their Figure 1) showed an obvious lack of agreement between the isochrones and the cluster photometry in the region of the RGB. Indeed, the confidence in ages derived from theoretical isochrones is higher if the isochrone is able to reproduce the complete trend defined by the cluster photometry from the lower main sequence to the tip of the RGB. Therefore, reliable *uvby* colors are required to transform the isochrones before any definite conclusion can be made regarding cluster ages.

Despite the potentials Strömgren photometry holds for deriving distance independent ages for GCs, no attempt will be made here to reach any definite conclusions regarding cluster age or distance. Rather, the main goal of this section is to assess the consistency of the Strömgren C-T relations with those adopted by Vandenberg (2000) on various broadband CMDs. For such a purpose, a number of prominent GCs spanning a wide metallicity range is employed which have precise *uvby* and *BVI* photometry.

Before continuing with the present discussion, a few things should be noted concerning the isochrones and photometric data used here. First, the isochrones employed throughout this section have been derived from the Vandenberg et al. (2000) evolutionary tracks using the interpolation techniques described by Bergbusch & Vandenberg (2001). These models have been computed for 17 $[\text{Fe}/\text{H}]$ values ranging from -2.31 to -0.30 employing the most up-to-date physics and opacity data available and account for enhancements in α element abundances by assuming $[\alpha/\text{Fe}] = 0.0, +0.3,$ and $+0.6$ for each metallicity value. Cluster metallicity estimates are taken from Zinn

& West (1984, hereafter ZW) while reddening values are derived from the reddening maps of Schlegel et al. (1998, hereafter SFD) unless otherwise noted. In addition, a value of $[\alpha/\text{Fe}] = +0.3$ is generally adopted for all the GCs presented here (Carney 1996). Regarding isochrones fits to the photometric data, the same basic requirements which were adhered to in the previous section for OCs are also adopted here to the GC CMDs. Finally, the cluster CCD photometry has been graciously provided by F. Grundahl as part of his extensive and unprecedented *uvby* photometric survey of a large sample of globular and open clusters (see Grundahl et al. 1998, 1999, 2000a, and 2000b for details regarding the observational procedures and photometric reductions as well as in-depth investigations of the cluster properties, including distance and age).

4.2.1 M 92

The globular cluster M 92 serves as a representative of the oldest and most metal-poor clusters in the present sample. The ZW metallicity scale provides a value of $[\text{Fe}/\text{H}] = -2.24$ for the cluster, whereas Sneden et al (1991) and Carretta & Gratton (1997) have derived -2.25 and -2.16 , respectively, on the basis of high-resolution spectroscopy of cluster giants. In addition, the reddening of the cluster is similarly well constrained, with the SFD reddening maps giving $E(B - V) = 0.023$. Figure 4.9 presents the observed *uvby* CMDs for M 92 along with the corresponding best fitting 16 Gyr isochrone transformed to each indicated color (note that this age estimate is reduced by 10 - 12 % when diffusive processes are taken into account - see Vandenberg et al. 2001, in preparation). For the purpose of the fit, an isochrone corresponding to $[\text{Fe}/\text{H}] = -2.31$ is preferred based on the metallicity estimates mentioned above.

Overall, the isochrone fits to the M 92 CMDs appear to agree remarkably well with each other when a distance modulus of $(m - M)_V = 14.55$ and the SFD reddenings are adopted. The only mentionable discrepancy is the moderately large color shift

required to match the data on the $[(u - y), M_V]$ plane. Concerning this matter, Grundahl et al. (2000a) have noted that their u magnitudes for M92 could suffer from a zero point problem as large as 0.04 mag, which might explain the reason for such a needed shift in color. Regardless of the cause, the validity of the calibrated Strömgen colors for extremely low metallicities is confirmed in all four panels of Figure 4.9 by the fact that the isochrone matches all components of the CMDs from the MS to the RGB.

While Figure 4.9 compared isochrone fits on various Strömgen color planes, Figure 4.10 presents a similar comparison between a $(b - y)$ CMD and its broadband equivalents. The BV fiducial sequence plotted in panel (b) has been taken from Stetson & Harris (1988) while the VI data in panel (c) comes from the study of Johnson & Bolte (1998). In each panel a number of isochrones are plotted ranging in age from 8 to 18 Gyr in steps of 2 Gyr and corresponding to the same metallicity considered above. In addition, the same SFD reddening is adopted to correct the photometry for each case. The only parameter which is notably different between this figure and the previous one is the slightly larger distance modulus of 14.59 adopted on the basis of fits to all three color planes which suggests there are slight differences in the V magnitude scales in these investigations. From inspection of this figure, it is immediately evident that the same 16 Gyr, $[\text{Fe}/\text{H}] = -2.31$ isochrone yields the same basic interpretation of the data regardless of which photometric color is adopted. Not only does this lend reassurance to the accuracy of the calibrated Strömgen colors, but also for the T_{eff} scale predicted by the isochrones.

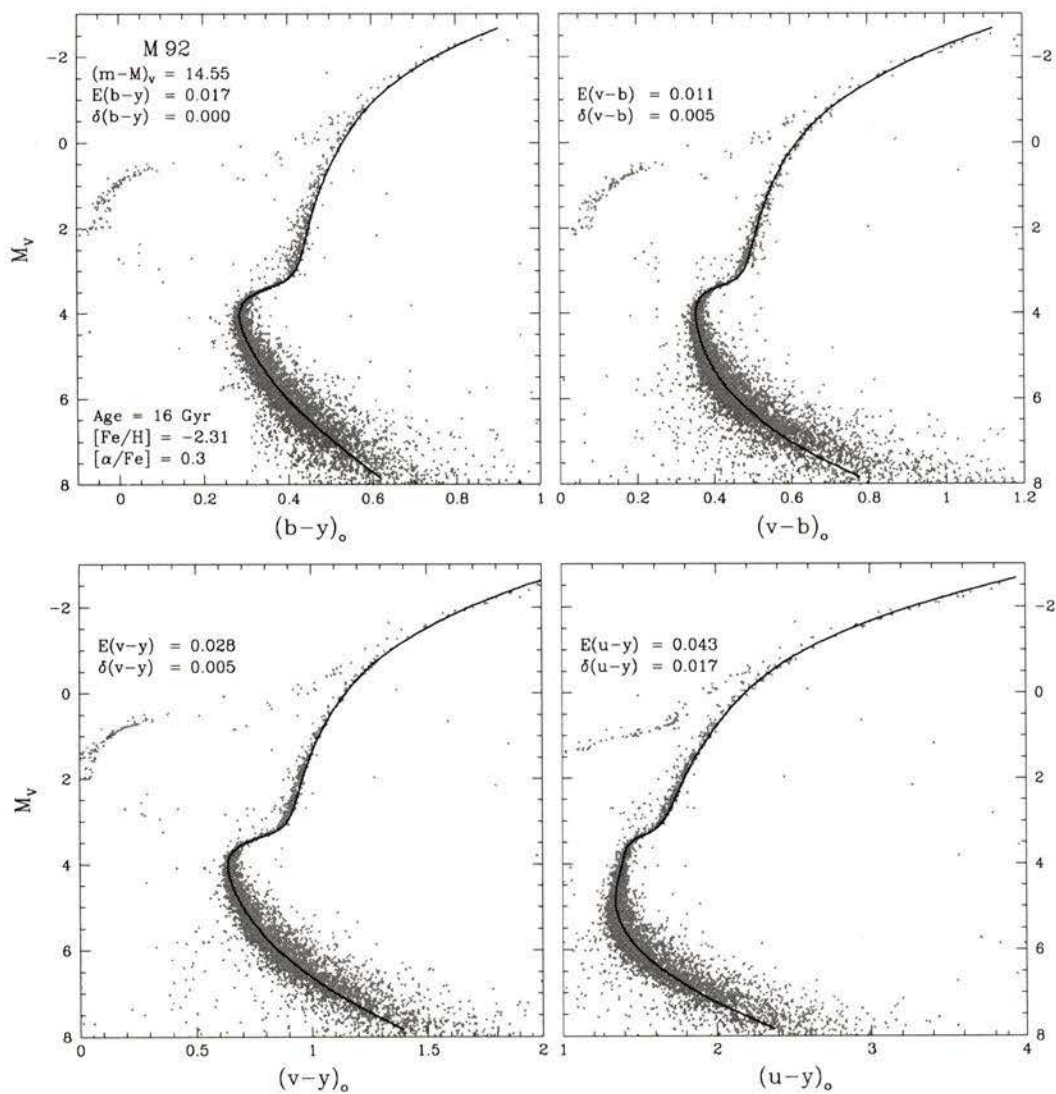

Figure 4.9: Fits of a 16 Gyr isochrone for the indicated parameters to the various *uvby* CMDs of M 92.

Figure 4.10: Fits of isochrones to the indicated Strömgen and broadband CMDs for M 92. The BV fiducial sequence is taken from Stetson & Harris (1988) whereas the VI fiducial is from the study of Johnson & Bolte (1998).

4.2.2 M 13 and NGC 288

M 13 and NGC 288 are chosen as the best examples of two intermediate metallicity globular clusters with ZW $[Fe/H]$ values of -1.65 and -1.40 , respectively. As with M 92, Figures 4.11 and 4.12 illustrate the superb quality of the isochrone fits among various Strömgen CMDs for both clusters. For each case, the isochrone adopted for each cluster has a metallicity which closely corresponds to the ZW values mentioned above, and the distance moduli are tentatively estimated based on the agreement of fits on different color planes. Moreover, it appears M 13 is best fit with a 16 Gyr isochrone, while NGC 288 tends to favor a slightly younger age of 14 Gyr. The only possible problem worth noting is the rather large color shifts required to match to data for NGC 288 for the majority of colors presented in Figure 4.12. While the discrepancies in the $(u - y)$ plane for both NGC 288 and M 13 could be attributed to the same reason mentioned above for M 92, it is rather surprising such large shifts in

color are needed for the $(v-b)$ and $(v-y)$ colors. One possible explanation lies in the fact that NGC 288 could be slightly more metal-rich than quoted by ZW. Indeed, fits to the broadband CMDs for NGC 288 (see, e.g., Figure 28b of Vandenberg 2000b) indicate that a $[\text{Fe}/\text{H}] = -1.31$ isochrone can provide an adequate fit to the cluster fiducial if a SFD reddening is assumed.

Turning to Figures 4.13 and 4.14 for the comparisons of $uvby$ and broadband CMDs, it is quite evident that the results yield excellent consistency between the fits for both clusters. However, it is not clear why such a large, negative color shift is required to match the VI fiducial for M 13.

Figure 4.11: Fits of a 16 Gyr isochrone for the indicated parameters to the various *uvby* CMDs of M13.

Figure 4.12: Fits of a 14 Gyr isochrone for the indicated parameters to the various *uvby* CMDs of NGC 288.

Figure 4.13: Fits of isochrones to the indicated Strömgen and broadband CMDs for M 13. The VI fiducial sequence is taken from Johnson & Bolte (1998).

Figure 4.14: Fits of isochrones to the indicated Strömgen and broadband CMDs for NGC 288. The BV fiducial sequence is derived from the photometry of Bolte (1992).

4.2.3 NGC 104

The final GC to be investigated is NGC 104 (47 Tucanae), and with current metallicity estimates for the cluster hovering around $[\text{Fe}/\text{H}] \approx -0.7$, it is one of the most metal-rich GCs known. Figure 4.15 further indicates that it is also the youngest among the GCs discussed here with an age of 13 Gyr. While this age as well as the adopted distance modulus differ by ≈ 1 Gyr and ≈ 0.1 mag, respectively, from those adopted by VandenBerg (2000), they do agree quite well with the recent values of $(m - M)_V = 13.27 \pm 0.14$ and 13 ± 2.5 Gyr obtained from comparisons of white dwarfs within the cluster to their counterparts in the field (Zoccali et al. 2001). One other point concerning the $(u - y)$ fit in Figure 4.15 should be noted, specifically, the rather large color shift which has plagued the same colors for previous clusters is not needed here for NGC 104. Why a moderately large color shift was needed before and not now is not immediately clear.

For the purposes of comparing Strömgren and broadband data fits, Figure 4.16 employs the BV and VI data of Kaluzny et al. (1997, 1998). However, one immediate problem is apparent in panels (b) and (c) of the figure. In particular, rather large color offsets are required to fit the broadband data. The explanation for this discrepancy could lie in the fact 47 Tuc might be slightly more metal-poor than the ZW estimate used here. Indeed, VandenBerg (2000) has obtained more agreeable fits using the $[\text{Fe}/\text{H}] = -0.83$ grid of isochrones to the composite BV fiducial of Hesser et al. (1987).

Figure 4.15: Fits of a 13 Gyr isochrone for the indicated parameters to the various *uvby* CMDs of NGC 104.

Figure 4.16: Fits of isochrones to the indicated Strömgen and broadband CMDs for NGC 104. The BV and VI photometric data are taken from the studies of Kaluzny et al. (1997, 1998).

Chapter 5

Conclusions

Owing to the superb quality of the isochrone fits to the various open and globular cluster *uvby* CMDs presented in the previous chapter, it is quite apparent that the color calibrations derived from the field star sample have adequately placed the synthetic Strömgren colors onto the same system as the observational data. Indeed, additional tests involving *uvby* photometry for other clusters from the observational surveys of F. Grundahl (e.g. M 3, NGC 362, NGC 1851, M 71, and NGC 6791), which are not discussed in the present work, likewise yield the same excellent agreement between the appropriate isochrone and cluster CMDs from the main sequence through the red giant branch. Equally important is the fact that these newly calibrated Strömgren C-T relations are able to provide similar interpretations of the *uvby* photometric data when compared to isochrone fits involving the same clusters observed in the broadband (*UBVRI*) system.

Although this work has attempted to assess the validity of the Strömgren colors by testing them against both the field stars used to calibrate them as well as a number of star clusters with new and accurate *uvby* photometry, this type of study could undoubtedly benefit from additional observational data, particularly for clusters. Apart from the cluster survey of F. Grundahl, a variety of very recent works

have reported precise CCD *uvby* photometry for other clusters such as NGC 6397, M 22, M 55, NGC 5139, and IC 4651 (see Anthony-Twarog & Twarog 2000, Richter et al. 1999, Hilker & Richtler 2000, and Meibom 2000) and have greatly increased the amount of *uvby* data currently available. Regardless of this fact, however, the quantity of cluster data in the broadband system still far outweighs that in the Strömgren system. More *uvby* data would in turn mean more opportunities to constrain the accuracy of the calibrated colors and to investigate consistencies between the two photometric systems in interpreting clusters CMDs.

While currently available synthetic Strömgren C-T relations are reasonably successful in reproducing the colors of warmer stars (i.e. $T_{\text{eff}} > 8000\text{K}$; see discussions by Relyea & Kurucz 1978 and Castelli 1991), it is nevertheless important to also test the colors outside of the temperature range considered here. One feasible way of doing this involves transforming Zero Age Horizontal Branch (ZAHB) models to the observations and comparing them to the actual distribution of horizontal branch stars in a cluster CMD. Although the results of such investigations are not discussed in the present work, the warmer colors do in fact yield good fits of the ZAHB models to horizontal branches of the same GC sample used in the last chapter.

Apart from providing the reliable means by which to transform theoretical stellar models to the observational plane so they may be readily compared to *uvby* photometric data, there are a number of other areas where these new Strömgren C-T relations can prove useful in cluster studies, some of which are discussed briefly in the following:

- *Distance independent GC ages.* The newly calibrated C-T relations can be used to derive more reliable, distance-independent ages for globular clusters using techniques akin to those described in Grundahl et al. (2000a) for M 92. This would prove most helpful not only in resolving the distance scale controversy briefly discussed in the previous chapter, but also in constraining the age of the

oldest globular clusters which can ultimately place a lower limit on the age of the universe.

- *Cluster [Fe/H] estimates from GC red giant stars.* A number of studies have demonstrated the usefulness of Strömgren m_1 index in providing independent [Fe/H] estimates for red giant stars in globular clusters. However, a recent examination by Anthony-Twarog & Twarog (2000) illustrates that the isometallicity relations for red giants determined from the previous work of Anthony-Twarog & Twarog (1994), Grebel & Richtler (1992), and Hilker (2000) are not in good agreement with each other despite being derived from comparable samples of metal poor stars. Here, the Strömgren C-T relations offer the ability to provide a new and accurate metallicity calibration for GC red giants based on the fact these colors have already been calibrated against a sample of metal poor field giants stars and have also proven to provide excellent agreement to the red giant branches of globular clusters covering a wide range in metallicity.
- *Abundance variations in GC giant stars.* From the analysis of Grundahl et al. (1998, 2000b) it is apparent that the significant spread in c_1 colors seen among GC red giant stars could be due to variations in the abundances of C, N, O, Mg, and Al perhaps caused by deep mixing during post main sequence evolution. While the current set of C-T relations are computed and calibrated on the assumption of scaled solar abundances with only a +0.3 dex enhancements to the α process elements, it is unlikely they would be unable to adequately reproduce the colors of RGB stars with significant elemental anomalies. However, a new set of synthetic colors for cool RGB stars could be calculated on the basis of model spectra which account for various mixes and abundance differences among certain elements and then placed onto the observed system using the calibrations derived in this work. The resulting colors could likely provide a means by which to photometrically constrain which elements and to what

extend their abundances have been enhanced in RGB stars as well as isolate certain stars which might deserve further detailed spectroscopic analysis.

In addition to these possibilities, the new Strömgren C-T relations can also prove useful in applications to stars outside of the cluster environment. For instance, the calibrated grids would allow accurate estimates for a star's temperature, gravity, and metallicity to be obtained solely from the knowledge of its colors indices. By combining such information for a large sample of field stars with the parallax and proper motion data from the *Hipparcos* could prove useful in investigating the spatial distribution and kinematics of stars with different metallicities in the solar neighborhood.

In closing, the promise that the Strömgren photometric system holds for increasing our understanding of stellar populations is undeniable. From its ability to provide precise estimates of T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ on a star-by-star basis, to its numerous applications to cluster studies, *uvby* photometry has proven itself as a powerful and accurate tool for observers and theorists. Given these facts, as well as the discussions and results presented here, it is anticipated that the Strömgren photometric system will gain increased recognition as a viable alternative to the *UBVRI* system for the examination of individual stars and stellar populations.

Appendix A

The Field Star Sample

The following pages list the field stars used to calibrate the synthetic Strömgren colors. The final column denotes the source of the T_{eff} , $\log g$, and $[\text{Fe}/\text{H}]$ information: 1=Houdashelt et al (2000b), 2=Alonso et al. (1996a), and 3=Alonso et al. (1999). The *uvby* photometry for each star has been taken from the catalog of Hauck & Mermilliod (1998) while the parallaxes and broadband photometry are from the *Hipparcos* catalog of Perryman et al. (1997). Photometric colors have been dereddened by the $E(b - y)$ values listed in the table. Histograms showing the number distribution of the field stars in terms of effective temperature and metallicity are shown in Figure A.1.

Figure A.1: Histograms showing the number distribution of field stars from Table A.1 in terms of T_{eff} and $[\text{Fe}/\text{H}]$. All dwarf stars in the sample are represented by the solid lines while dashed lines are the giant stars.

Appendix B

The Calibrated Strömgren Colors

The following appendix presents the entire Strömgren grid of colors calculated using the methods discussed in Chapter 2 and subsequently placed onto the observational system using the calibrations derived in Chapter 3. The Strömgren indices ($b - y$), m_1 , and c_1 are tabulated according to the effective temperatures, surface gravities, and metal abundances listed in each table.

Table B.1:

T_{eff}	$\log g$	$(b-y)$	m_1	c_1	T_{eff}	$\log g$	$(b-y)$	m_1	c_1
$[M/H] = 0.5$

Appendix C

Strömgren Photometry of NGC 188 and NGC 6819

The photometric observations of NGC 188 and NGC 6819 in the *uvby* filter set were obtained over three separate runs in September/October 1999 using the 1.8 meter Plaskett Telescope at the Dominion Astrophysical Observatory. The thinned SITE-5 CCD detector used for the observations was composed of an array of 1024 x 1024 pixels and yielded an effective field of view of 9.2' x 9.2'. The log of the cluster observations providing such information as the date, filter/exposure combinations, and airmass is given in Table C.1.¹ Atmospheric conditions throughout each of the 7 nights remained quite stable and lead to photometric skies for all three runs with average nightly seeing ranging between 2.05" and 2.73".

All initial science images were pre-processed using a number of bias frames and sky flats taken during the evening and morning twilight of each night. A total of 20 individual bias frames per night were median combined into a single master bias which was subsequently subtracted from the rest of the images. In addition, a medianed master flat for each Strömgren filter was produced from no fewer than 10 sky flats per night and used to account for the effects of pixel-to-pixel variations and gradients

¹Due to the fact that the filter wheel on the telescope could only accommodate two Strömgren filters at a time, observations were limited to using a combination of *uy* and *vb* filters on separate nights.

Table C.1: Journal of *uvby* observations for NGC 188 and NGC 6819.

in each image.

Several bright and isolated Strömgren standard stars taken from the lists of Crawford & Barnes (1970b) and Perry, Olsen, & Crawford (1987) were observed in conjunction with the cluster images to derive the transformations between instrumental magnitudes and the standard *uvby* system. To account for uncertainties in the timing of the camera shutter, all standard stars (as well as the cluster fields) required integration times of at least five seconds. This fact posed a problem, however, for these bright field standards because they saturated the chip in this minimum exposure time. To avoid saturation, the telescope was defocused by a small amount to allow the light from each standard star to be distributed over a larger area in the image. During the reduction process, the instrumental magnitudes for each standard were derived using aperture photometry while taking into careful consideration an aperture size which would be large enough to account for broad distribution of light over a large number of pixels, but small enough to both limit the amount of sky as well as ensure that light from neighboring stars did not enter into the aperture. After inspection of all standards on all frames, it was concluded that apertures with radii between of 25-30 pixels were sufficient enough for such considerations. Despite this, 5 standards were eventually discarded from subsequent photometric reductions because either their light distributions extended beyond the edge of the largest aperture or there was light contamination from other nearby defocused stars.

In addition to the primary field standards mentioned above, a number of stars from the open cluster NGC 752 were also observed and used as secondary standards (Crawford and Barnes, 1970a). These cluster stars were chosen largely because they were faint enough to avoid saturation of the chip without defocussing the camera. This fact allowed for a direct investigation of any possible differences between color transformations derived from the defocused standards and the cluster standards. The inclusion of the stars from NGC 752 also led to a slight increase in the color range for the standard transformations. In total, no fewer than 21 standard stars were used for

each night of observation to derive the transformation coefficients in every Strömgren filter (see below).

Images taken of both NGC 188 and NGC 6819 focused primarily on the cluster centers in order to maximize the number of stars. Due to the relative sparseness of NGC 188, however, additional observations of the four quadrants surrounding the cluster center were made in all four Strömgren filters. The photometric reduction of the cluster frames was performed using point spread function (PSF) photometry as part of the DAOPHOT II suite of programs (Stetson 1987). In summary, between 70 and 95 uncrowded and unsaturated stars in each cluster frame were used to construct a high signal-to-noise PSF. This PSF was then fitted to all stars detected on an individual frame under the assumption it was allowed to vary quadratically across the image. To ensure that the majority of stars had been detected, the resulting subtracted image from the PSF fitting routine was scanned for any faint and/or blended stellar images which were not detected during the initial run.

After all the cluster frames were reduced in the manner mentioned above, a set of coordinate transformations were derived to refer positions of each star on each frame to the coordinate system of a single master frame. These coordinate transformations along with a list of stellar positions on each frame were then fed into the multiple-PSF fitting ALLFRAME algorithm (Stetson 1994) which yielded the final PSF photometry for all detected stars and all frames. A total of 40 relatively bright and isolated stars were then selected from the photometry files and used to derive the aperture corrections. These corrections, defined as the net differences between a star's profile-fitted magnitude and its total magnitude as measured through a generously large aperture (typically containing $> 99\%$ of the total light), were determined by constructing a set of empirical growth curves using the DAOGROW program (Stetson 1990). For this procedure, all neighboring stars were first subtracted from the frames leaving only the 40 selected stars. The analysis proceeds by measuring stellar magnitudes through a set of concentric apertures centered on each star and selecting only those magnitudes

which had errors less than 0.01 mag to define the growth curve. The final aperture corrections were subsequently determined from the overall convergence of a large number of stellar growth curves and applied to the instrumental PSF magnitudes for each star.

The final step in the photometric reduction process is the transformation of the raw, instrumental magnitudes derived from PSF fitting and aperture corrections to the standard *uvby* system. After examination of the residuals between the standard and observed magnitudes for all standard stars and testing their dependence against any parameter that could correlate with the residuals (i.e. airmass, exposure time, photometric color, etc.), the final adopted transformation equations took the following form for each Strömgren filter:

$$m_{inst} = M_{std} + AX + B(v - y)_{std} + C \quad (\text{C.1})$$

where M_{std} and m_{inst} are the standard and instrumental *uvby* magnitudes for each star in question and X and $(v - y)_{std}$ are the airmass and photometric color of the standard star, respectively. The three coefficients listed in the above equation (A , B , and C) were solved by the method of simultaneous least-square fitting. Table C.2 provides the values of these coefficients for each night of observation. Once the transformation coefficients were derived, a number of bright isolated stars in each cluster were transformed to the standard system to serve as local zero-point standards. These local standards were then used to transform the instrumental magnitudes of all other detected stars in all cluster frames to the standard *uvby* system.

Table C.2: The transformation coefficients for the Strömgren standard star observations. For all Strömgren filters the transformation equations took the form $m_{inst} = M_{std} + AX + B(v - y)_{std} + C$. Columns 6, 7, and 8 provide the number of standard stars (N) together with their range in $(v - y)$ color and airmass (X) which were used to derive the transformations while column 9 denotes the *rms* (σ) of the resulting standard star residuals.

In regards to the photometric accuracy of the final calibrated photometry, Figure C.1 presents the computed residuals of the standard stars for each Strömgren filter. In all four panels, the plotted residual is computed as the difference between the observed magnitude (based on its weighted average over all nights the standard was observed) and the actual standard magnitude. Furthermore, filled circles are used to represent the bright field standards while open circles give the residuals for the secondary standard stars observed in NGC 752. The figure shows that there are no systematic trends of the residuals with magnitude. Furthermore, the secondary standard stars observed in NGC 752 not only extend down to fainter magnitudes in each filter, but also exhibit no obvious differences in residuals from the primary standards.

Samples of the final standard *uvby* photometry for both NGC 188 and NGC 6819 are provided in Tables C.3 and C.4. Since the photometry given here is the first of its kind published to date, no direct comparison between the present data and previous Strömgren studies of these two clusters can be presented. Both clusters, however, have been extensively surveyed in the past few years using broadband filters, and the photometric studies of Rosvick & Vandenberg (1998) for NGC 6819 and Sarajedini et al. (1999) for NGC 188 yield a large number of stars in common with the present study. Given that Strömgren *y* magnitudes are often equated to broadband *V*, Figure C.2 examines the differences between *y* and *V* for stars in common between the present photometry and the two studies mentioned above. For each cluster, the comparison involves stars selected on the criteria that their photometric uncertainties are less than 0.015 mag in both *y* and *V*. For NGC 6819 the average difference between magnitudes denoted in the panel is negligible while it is just slightly less 0.01 mag for NGC 188. For both clusters, there appears to be quite good agreement between the Strömgren *y* and broadband *V* magnitudes with no obvious trends in the data, though there is an increased scatter toward fainter stars.

Figure C.1: Residuals between the computed and standard magnitudes for 51 standard stars observed in conjunction with the cluster observations. Each panel plots the residual versus standard magnitude for each Strömgren filter along with their computed means and standard deviations. Solid circles indicate field standards while open circles are the secondary standard stars observed in the open cluster NGC 752.

Figure C.2: A comparison between Strömgren y magnitudes derived in this study and broadband V magnitudes taken from the studies of Sarajedini et al. (1999) for NGC 188 and Rosvick & Vandenberg (1998) for NGC 6819. The computed averages are based on the number of stars indicated in each panel which have photometric uncertainties less than 0.015 mag in both y and V .

Table C.3: A sample of the final *uvby* photometry for a total of 1128 stars detected in NGC 188. For each star listed in the first column, the global CCD x and y positions, individual *u*, *v*, *b*, and *y* magnitudes on the standard system along with their corresponding mean errors, and the number of detections are given the remaining columns.
