## Abstract

---

Nitrous oxide ( $\text{N}_2\text{O}$ ) is a potent greenhouse gas with a high global warming potential, but the underlying processes behind  $\text{N}_2\text{O}$  production and consumption are not well understood. The ocean is known to be a strong source of  $\text{N}_2\text{O}$  to the atmosphere, yet ocean  $\text{N}_2\text{O}$  production is poorly constrained at anywhere from 10 to 53% of the total  $\text{N}_2\text{O}$  atmospheric source. In order to narrow down estimates of net  $\text{N}_2\text{O}$  production in the ocean, I have created a steady state model to explore the uncertainties involved in the biological processes that contribute to  $\text{N}_2\text{O}$  production and consumption (nitrification and denitrification). Model results show that oxygen and organic matter supply strongly control  $\text{N}_2\text{O}$  production and consumption rates, and also demonstrate strong dependence on parameters such as the oxygen threshold for oxic versus suboxic remineralization, the oxygen concentration dependence of  $\text{N}_2\text{O}$  reduction to  $\text{N}_2$ , the proportion of suboxic and oxic remineralization in relation to oxygen, and the attenuation length scale of sinking organic matter. Additionally, I find that global net  $\text{N}_2\text{O}$  production rates are heavily influenced by the oxygen data input into the model: interpolation of oxygen data or averaging of monthly oxygen data to an annual mean can lead to underestimation of denitrification. As suboxic conditions are required for denitrification to produce (and consume)  $\text{N}_2\text{O}$ , precise and accurate oxygen data is integral to constraining estimates of global ocean  $\text{N}_2\text{O}$  production.

The results of the base case scenario of the model, as well as from a number of sensitivity experiments, indicate that the source and sink terms for  $\text{N}_2\text{O}$  production are larger than suggested by many past models.  $\text{N}_2\text{O}$  production and consumption by denitrification are high in oxygen deficient zones ( $19.2 \text{ Tg-N y}^{-1}$  and  $8.37 \text{ Tg-N y}^{-1}$ , respectively) while global total nitrification production is low ( $0.740 \text{ Tg-N y}^{-1}$ ).  $\text{N}_2\text{O}$  production by denitrification is primarily responsible for generating relatively high net  $\text{N}_2\text{O}$  production rates in the global ocean ( $11.5 \text{ Tg-N y}^{-1}$  for the base case scenario), and likely provide a greater proportion of global  $\text{N}_2\text{O}$  emissions to the atmosphere than many previous estimates. Model representation of denitrification production and consumption rates is highly sensitive to changes in oxygen concentration and parameters related to oxygen, suggesting that altered ocean environments due to future climate change may have a large effect on  $\text{N}_2\text{O}$  production in the ocean. This research isolates the uncertainties that most impact  $\text{N}_2\text{O}$  production and consumption processes and suggests pathways of future research to narrow down these uncertainties. In particular, I recommend more in-situ oxygen sampling with high precision and accuracy (especially in oxygen deficient zones), experimental research to constrain important parameters, and separation of  $\text{N}_2\text{O}$  production by nitrification,  $\text{N}_2\text{O}$  production by denitrification, and  $\text{N}_2\text{O}$  consumption by denitrification in future model development (as in this model).

# List of Figures

Figure 1: Nitrogen Cycle Diagrams. Top image shows the full scope of the nitrogen cycle from Pajares & Ramos 2019, while the bottom image is processes that are directly relevant to N <sub>2</sub> O and that are included in this model. ....	3
Figure 2: Illustrations of where relevant N <sub>2</sub> O reactions (rem mineralization, nitrification, and denitrification) occur in relation to dissolved O <sub>2</sub> concentrations in the ocean, with a focus on oxygen deficient zones (ODZs).....	5
Figure 3: Global N <sub>2</sub> O budget with sources and sinks (from Tian et al. 2020) .....	7
Figure 4: Effect of temperature on rem mineralization using the Arrhenius Equation ( $T_g$ ) .....	13
Figure 5: Fraction of suboxic rem mineralization, $\Omega$ (red), and oxic rem mineralization, $1-\Omega$ (blue), at O <sub>2</sub> concentrations in the suboxic range from 0-6 $\mu\text{mol-O}_2 \text{ L}^{-1}$ . ....	14
Figure 6: $fNO_{3,remin}$ versus NO <sub>3</sub> <sup>-</sup> (top), and relationship of $(fNO_{3,remin})(\Omega)$ , NO <sub>3</sub> <sup>-</sup> , and O <sub>2</sub> (bottom). ....	16
Figure 7: Percent yield of N <sub>2</sub> O from nitrification versus O <sub>2</sub> concentrations. ....	18
Figure 8: Inhibition of nitrification by solar irradiance. Top panel shows a one-dimensional depth profile using annually and globally averaged surface solar irradiance ( $E_0$ ), bottom panel uses annually averaged zonal mean surface solar irradiance across various latitudes.....	19
Figure 9: $fO_{2,AmOx}$ versus O <sub>2</sub> . $fO_{2,AmOx}$ decreases the rate of nitrification as O <sub>2</sub> decreases, especially below approximately 10 $\mu\text{mol-O}_2 \text{ L}^{-1}$ . ....	20
Figure 10: Relative N <sub>2</sub> O consumption rate vs. O <sub>2</sub> concentration. ....	22
Figure 11: Surface PAR across varying latitudes. Top figure depicts annual averages, while bottom figure depicts monthly variations in PAR over the course of one year. Data from ISCCP (Bishop et al. 1997). ....	25
Figure 12: Regional variations in annual mean temperature at depths of 100 m (left), 300 m (middle), and 600 m (right). Data from World Ocean Atlas (Locarnini et al. 2018).....	26
Figure 13: Detritus flux ( $F_z$ ) with depth using export from the euphotic zone ( $F_{eu}$ ) and an inverse rem mineralization length scale ( $a_c$ ) of 0.003 $\text{m}^{-1}$ .....	27
Figure 14: A schematic of the chemostat, illustrating input and output variables and reaction processes. ....	30
Figure 15: Global Net N <sub>2</sub> O Production Rates at 250 m, on a linear (left) and logarithmic (right) colour scale.....	32
Figure 16: Global Net N <sub>2</sub> O Production rates across multiple depth layers from 150 m to 1000 m, using a logarithmic colour scale. Top panels (150-400 m) share a common color scale range, which is different from the color scale range used for the bottom panels (600-1000 m). ....	33
Figure 17: Global N <sub>2</sub> O production rates, including net production, production from nitrification, production from denitrification, and consumption by denitrification. Net production is 11.5 Tg-N $\text{y}^{-1}$ , with production by denitrification comprising the majority of global net production.....	34
Figure 18: Net N <sub>2</sub> O production rates in the North Pacific, along 120°W.....	35
Figure 19: Net N <sub>2</sub> O production rates in the North Atlantic, along 30°W. Note that the colour scale range is smaller than in Figure 18, as N <sub>2</sub> O production rates in oxic waters are much lower than those in suboxic waters. ....	36
Figure 20: N <sub>2</sub> O production rates by nitrification (left) and denitrification (right) for a transect along 120°W.....	37
Figure 21: Depth profiles for the North Pacific oxygen deficient zone (10°N, 120°W) (top) and the oxygenated North Atlantic (40°N, 30°W) (bottom). Vertical dashed line in oxygen concentration plots represent the O <sub>2</sub> threshold for suboxic rem mineralization at 6 $\mu\text{mol-O}_2 \text{ L}^{-1}$ . ....	38
Figure 22: The number of suboxic O <sub>2</sub> data points (0-6 $\mu\text{mol-O}_2 \text{ L}^{-1}$ ) for the unaltered 2018 World Ocean Atlas O <sub>2</sub> data (left), as well as the corrected O <sub>2</sub> data using a linear correction method from Bianchi et al. (2012) (right), where $[O_{2,corrected}] = 1.009*(O_{2,WOA})-2.523$ ( $\mu\text{mol-O}_2 \text{ L}^{-1}$ ). If $[O_{2,corrected}] < 0$ , concentration is set to zero. ....	40
Figure 23: Depth profiles of O <sub>2</sub> concentration in the North Pacific ODZ (10°N, 120°W), with original WOA 2018 data and WOA 2018 data with Bianchi et al. (2012) correction method. ....	41
Figure 24: Monthly variation in global net N <sub>2</sub> O production rates with monthly O <sub>2</sub> data (Garcia et al. 2018a). ....	42
Figure 25: Histogram of the number of suboxic oxygen data points (0-6 $\mu\text{mol-O}_2 \text{ L}^{-1}$ ) for the 2018 World Ocean Atlas data for annually averaged data (blue) and monthly data (red). Monthly data are normalized to the same number of data points as for the annually averaged data. ....	43
Figure 26: Global total N <sub>2</sub> O production rates using annually averaged O <sub>2</sub> data (blue) compared to using monthly O <sub>2</sub> data (red). ....	44

Figure 27: Number of suboxic O <sub>2</sub> data points (O <sub>2</sub> ≤ 6 μmol kg <sup>-1</sup> ) in the Eastern Pacific Ocean (50°S to 50°N, 180° to 80°W) uses three types of O <sub>2</sub> data products: Kwiecinski and Babbin (2021), WOA2018, and WOA2018 with Bianchi et al. (2012) correction.....	46
Figure 28: O <sub>2</sub> Concentrations using three different data sets - Kwiecinski and Babbin 2021 (blue), 2018 WOA (black), and Bianchi-corrected WOA2018 (red) - and net N <sub>2</sub> O production rates using these O <sub>2</sub> data products. When the difference between WOA2018 and Bianchi-corrected WOA2018 is negligible, the black WOA2018 line may not be visible. ....	50
Figure 29: Global N <sub>2</sub> O production rates using monthly or annually averaged export production (CanESM5-CanOE). The base case scenario (annually averaged export) is in bold. ....	53
Figure 30: Global N <sub>2</sub> O production rates using monthly or annually averaged export production (CanESM5-CanOE). ....	54
Figure 31: Export production of carbon from the euphotic zone as generated by five Earth System Models: CanESM5, CanESM5-CanOE, CNRM-ESM2-1, GFDL-ESM4, and UKESM1-0-LL. ....	55
Figure 32: Global N <sub>2</sub> O production and consumption rates using export production of particulate organic matter from the euphotic zone from different Earth System Models. Bottom panel depicts the nitrification production rates in the top panel at a larger scale. Base case (CanESM5-CanOE) is in bold. ....	56
Figure 33: Effect of changing the remineralization length scale on the attenuation of detritus flux with depth (top) and the rate of detritus input into each model layer (bottom). Base case scenario ( $\alpha_{RLS} = 0.003 \text{ m}^{-1}$ ) is in bold. ....	57
Figure 34: Effect of changing the inverse remineralization length scale ( $\alpha_{RLS}$ ) on global N <sub>2</sub> O production rates (using export production from CanESM5-CanOE). ....	58

## Dedication

---

I'd like to thank my supervisors and family for being patient, supportive, and understanding throughout the course of this research – especially as it took place during the course of the COVID19 pandemic. This thesis is dedicated to all students who kept up their studies during the pandemic and lockdown.

*“I wish it need not have happened in my time,” said Frodo.*

*“So do I,” said Gandalf, “and so do all who live to see such times. But that is not for them to decide. All we have to decide is what to do with the time that is given us.”*

-J.R.R. Tolkien, The Fellowship of the Ring

I'd also like to thank my friends and neighbours, who helped me stay sane when we were isolated and whose positive thinking ensured that this thesis reached its completion.

# 1 Introduction

---

Nitrous oxide ( $\text{N}_2\text{O}$ ) is a potent greenhouse gas that has a high Global Warming Potential and can contribute to anthropogenic climate change and ozone depletion, despite occurring in trace concentrations (Ravishankara et al. 2009, Portmann et al. 2012, Ciais et al. 2013, Müller et al. 2021).  $\text{N}_2\text{O}$ 's Global Warming Potential is 265-298 times that of carbon dioxide for a 100-year timescale, and  $\text{N}_2\text{O}$  gas emitted to the atmosphere can remain there for more than 100 years (Ciais et al. 2013, Makowski 2019). An estimated 10-53% of total  $\text{N}_2\text{O}$  sources are from ocean contributions (Anderson et al. 2010, Freing et al. 2012, Ciais et al. 2013, Bange et al. 2019). This large range of estimates demonstrates how global and regional  $\text{N}_2\text{O}$  emissions from the ocean are still not well constrained. This is in part due to a fundamental lack of understanding of the nitrogen cycle processes involved – particularly the contributions of nitrification and denitrification to  $\text{N}_2\text{O}$  production.

The extent of nitrification and denitrification in the ocean remains a subject of contention, as do rates of  $\text{N}_2\text{O}$  production and subsequent efflux from the ocean (Yool et al. 2007, Freing et al. 2012, Babbin et al. 2015, Battaglia and Joos 2018, Bange et al. 2019). Nitrification is known to occur in oxic waters, with reaction rates decreasing in suboxic concentrations while  $\text{N}_2\text{O}$  yield from nitrification increases as  $\text{O}_2$  decreases (Nevison et al. 2003, Grundle et al. 2012, Ji et al. 2018). Denitrification only occurs in suboxic waters, where  $\text{N}_2\text{O}$  is produced at a certain suboxic range of  $\text{O}_2$  but is consumed at extremely low, near-anoxic  $\text{O}_2$  concentrations (Dalsgaard et al. 2014, Babbin et al. 2015, Kelly et al. 2021). *In situ* measurements of  $\text{N}_2\text{O}$  production and consumption rates by these processes report a wide range of values that are affected by both oxygen and organic matter supply, making the degree to which these reactions are controlled by environmental conditions and substrate availability difficult to determine. Researchers have found some success in estimating a range of global net  $\text{N}_2\text{O}$  production rates using modelling and laboratory data, but the scale at which each process contributes to the global ocean's production of  $\text{N}_2\text{O}$  is not completely understood and so resulting production rates are often poorly defined (Zamora and Oschlies 2014, Babbin et al. 2015, Battaglia and Joos 2018, Tian et al. 2020). In a changing climate, the magnitude and distribution of nitrification or denitrification in various regions of the ocean may change (Codispoti 2010, Martinez-Rey et al. 2015, Battaglia and Joos 2018). This could mean a substantial change in the outgassing of greenhouse gases in some regions.

This research models the contributions to  $\text{N}_2\text{O}$  production from nitrification and denitrification in order to clarify what changes in environmental conditions will most affect ocean  $\text{N}_2\text{O}$  emissions. In doing so, the key controls and uncertainties of these processes will be identified, highlighting the missing observational data most crucial to improving understanding of  $\text{N}_2\text{O}$  production. The results from this model, corroborated by quantifications of additional uncertainties, aim to improve accuracy of future Earth System Models.

The marine nitrogen cycle controls the ocean's productivity through nutrient availability (Gruber and Galloway 2008, Lam and Kuypers 2011), but the ongoing discovery of new processes and organisms complicates mathematical representation of the processes involved (Capone et al. 2008, Kalvelage et al. 2011, Thamdrup 2012). As anthropogenic change affects biogeochemical processes in new and often unexpected ways, understanding the existing nitrogen cycling pathways and mechanisms of  $\text{N}_2\text{O}$  production will become increasingly important (Codispoti et al. 2001, Bange et al. 2019). To better anticipate the future ecosystem our society will inhabit it

is imperative that marine scientists understand what nitrogen cycling pathways occur, the relevant reaction rates, and how they may change in the future.

Nitrogen cycling processes that impact  $\text{N}_2\text{O}$  production are shown in Figure 1 below, although the representation of these processes in the mathematical model will be condensed and simplified (especially in the case of denitrification). Remineralization of organic nitrogen ( $\text{N}_{\text{org}}$ ) produces ammonium ( $\text{NH}_4^+$ ), which can then undergo nitrification to produce nitrate ( $\text{NO}_3^-$ ) and, as a by-product, nitrous oxide ( $\text{N}_2\text{O}$ ). In low oxygen conditions ( $\text{O}_2$  less than approximately  $6 \mu\text{mol-O}_2 \text{ L}^{-1}$ ), denitrification occurs through reduction of nitrate and nitrite ( $\text{NO}_2^-$ ) to nitrous oxide as well as reduction of nitrous oxide itself to dinitrogen ( $\text{N}_2$ ).

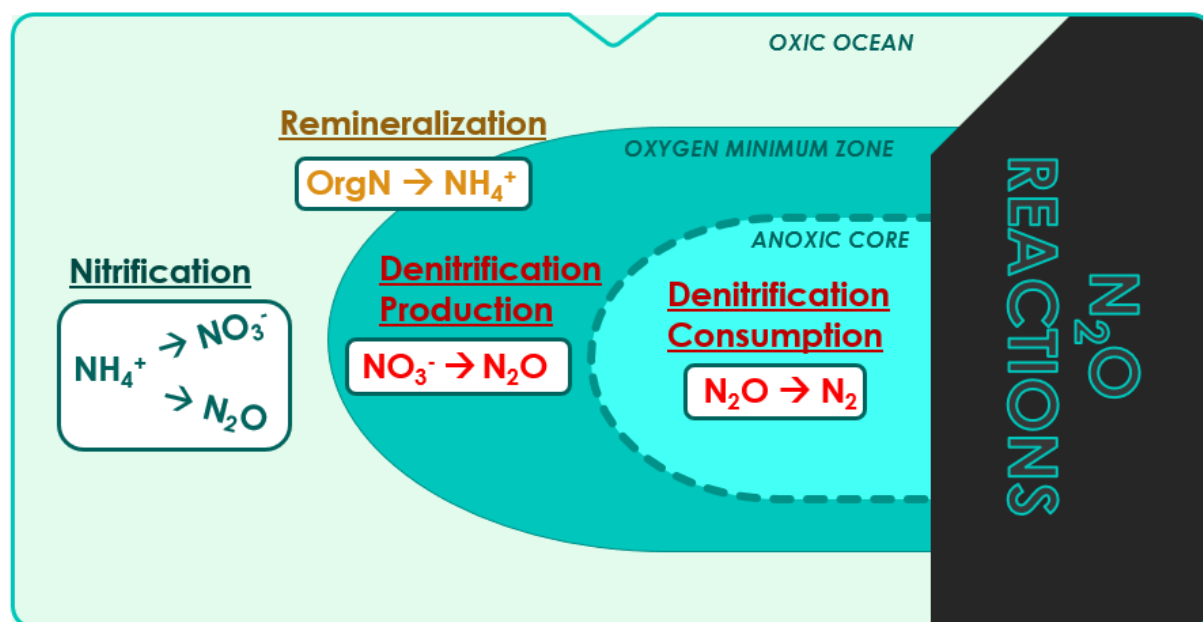

Nitrification and denitrification pathways will be emphasized for the purpose of this study due to their direct contributions to N<sub>2</sub>O production, although there are other as-yet unverified biological sources or sinks for N<sub>2</sub>O that are neglected here due to lack of concrete information. Some of these processes include anaerobic ammonium oxidation (anammox) (Dalsgaard et al. 2012) and dissimilatory nitrate reduction to ammonium (DNRA, or nitrate/nitrite ammonification) (Lam and Kuypers 2011). Additionally, recent research suggests that there may be a substantial difference in the reaction kinetics and controls on nitrification between bacteria and archaea (Löscher et al. 2012, Casciotti et al. 2018, Santoro et al. 2021, Kelly et al. 2021), indicating that models may need to parameterize different pathways for bacterial and archaeal nitrification. Unfortunately, current lack of information on these processes has made it difficult to approximate their relative importance in global estimates of N<sub>2</sub>O production.

As an example, pathways for N<sub>2</sub>O production by nitrification by bacteria versus archaea might differ in O<sub>2</sub> tolerance and reaction kinetics. This would directly affect the amount of N<sub>2</sub>O produced by nitrification, but the degree to which these organisms differ - and the manner in which they differ - is not yet confirmed or fully quantified (Trimmer et al. 2016, Casciotti et al. 2018, Santoro et al. 2021). In addition to NH<sub>4</sub><sup>+</sup> oxidation by bacteria and archaea, other N-removal pathways could affect N<sub>2</sub>O production. While anammox and DNRA do not directly produce N<sub>2</sub>O, they affect substrate availability (NH<sub>4</sub><sup>+</sup>, NO<sub>3</sub><sup>-</sup>) and occur in suboxic waters where there is strong production and consumption of N<sub>2</sub>O by denitrification. However, although anammox and DNRA have been observed *in situ*, the data needed for parameterizing reaction pathways and establishing the relative importance of these processes (compared to nitrification and denitrification) in the ocean nitrogen cycle and N<sub>2</sub>O production are still lacking.

*Nitrification* is the oxidation of ammonium to nitrate through two phases - ammonium oxidation and nitrite oxidation - and can produce N<sub>2</sub>O as a by-product (Yool et al. 2007, Capone et al. 2008, Rassamee et al. 2011, Lam and Kuypers 2011). Nitrification only occurs in oxygenated conditions; however, at low O<sub>2</sub> concentrations the yield of N<sub>2</sub>O (as opposed to NO<sub>3</sub><sup>-</sup>) increases substantially. Below a certain O<sub>2</sub> concentration *denitrification* also occurs to both produce and consume N<sub>2</sub>O depending on how far the reaction progresses. Because of this, N<sub>2</sub>O is an intermediate product of the denitrification reaction while it is a by-product of the nitrification reaction. Denitrification is also controlled by O<sub>2</sub>: if O<sub>2</sub> concentrations are suboxic but not anoxic then denitrification may be halted or severely hindered at the intermediate step before N<sub>2</sub>O reduction to N<sub>2</sub> (Dalsgaard et al. 2012, Babbín et al. 2015, Ji et al. 2018, Sun et al. 2021).

As most N<sub>2</sub>O production and consumption reactions are heavily affected by O<sub>2</sub> concentration, regions in and at the boundaries of oxygen deficient zones (ODZs) are highly relevant in researching the individual contributions of these reactions to N<sub>2</sub>O production. Maximum N<sub>2</sub>O concentrations and production rates have been recorded at the boundaries of ODZs and are considered to be caused by a combination of nitrification and denitrification processes occurring concurrently (Babbín et al. 2015, Trimmer et al. 2016, Sun et al. 2017, Ji et al. 2018, Rees et al. 2021). As ODZs are projected to expand due to anthropogenic climate change (Keeling et al. 2010, Schmidtko et al. 2017, Breitburg et al. 2018), the N<sub>2</sub>O produced in these regions is also anticipated to change - perhaps drastically (Codispoti 2010, Martinez-Rey et al. 2015, Battaglia and Joos 2018). The reactions relevant to N<sub>2</sub>O production and consumption are shown in relation to O<sub>2</sub> concentration in ODZs in Figure 2.

**Figure 2:** Illustrations of where relevant  $N_2O$  reactions (remineralsation, nitrification, and denitrification) occur in relation to dissolved  $O_2$  concentrations in the ocean, with a focus on oxygen deficient zones (ODZs).

In addition to  $O_2$  availability,  $N_2O$  production is affected by environmental conditions such as temperature, irradiance, and substrate supply (Babbin et al. 2015, Laufkötter et al. 2017, Ji et al. 2018, Battaglia and Joos 2018). By using computer model simulations to generate  $N_2O$  production rates, the sensitivity of nitrification and denitrification to  $O_2$  and these environmental conditions can be investigated. Improving the detail and accuracy of these simulations will aid in generating a more complex, realistic representation of the nitrogen cycling system and  $N_2O$  production from the ocean.

Due to the relevance of  $O_2$  in relation to  $N_2O$  production – especially in terms of denitrification – the size and intensity of oxygen deficient zones has substantial control over global  $N_2O$  production rates. ODZs are naturally occurring regions in the ocean where  $O_2$  reaches suboxic concentrations, even reaching near-zero concentrations in the cores of the ODZ. Often referred to as ‘shadow zones,’ ODZs are thought to originate from a combination of physical processes (such as weak ventilation) and biological processes (such as high productivity in surface waters) and typically occur near the western coastlines of continents at depths of around 200-1500 (Paulmier and Ruiz-Pino 2009, Ulloa et al. 2012). The strongest ODZs are in the Eastern Tropical North Pacific off the western coast of North America, the Eastern Tropical South Pacific off the coast of Peru, and in the Northern Arabian Sea. While ODZs are formed by natural processes, they are projected by global Earth System Models to expand due to effects of anthropogenic climate change (Stramma et al. 2008, Ciais et al. 2013).

Aside from oxygen, environmental conditions such as irradiance and temperature can control  $N_2O$  production reactions. Solar irradiance can inhibit nitrification, and the degree to which light permeates the ocean subsurface determines the depths at which nitrification can occur. The attenuation of light to  $< 1\%$  occurs at depths of approximately 100 m in clear waters, and below this depth the effects of irradiance on nitrification are minimized (Dore and Karl 1996).

Temperature is another relevant environmental condition within the scope of N<sub>2</sub>O production processes. Remineralization of organic matter is dependent on temperature and provides the initial reactants used in nitrification and denitrification reactions. Temperatures tend to be highest at the ocean's surface and vary regionally and seasonally, though similar to solar irradiance the variations in temperature greatly decrease below a certain depth.

Existing N<sub>2</sub>O production models have been developed and adapted to account for new data and observations over the past few decades, though there is no consensus on parameterization methods. Table 1 highlights global estimates from some of these models, where the wide range of global net N<sub>2</sub>O production rates illustrates how insufficient data impedes identification of uncertain parameters, contributing to poorly constrained estimates of N<sub>2</sub>O production in the ocean.

**Table 1:** Global Net N<sub>2</sub>O Production Rates

Author & Date	Global Net N <sub>2</sub> O Production Rate
Capone 1991	~10.5 Tg-N y <sup>-1</sup>
Suntharalingam, Sarmiento, and Toggweiler 2000	~3.85 Tg-N y <sup>-1</sup> (2.7-8.0 Tg-N y <sup>-1</sup> )
Codispoti et al. 2001	~6 Tg-N y <sup>-1</sup>
Nevison et al. 2003	~4 Tg-N y <sup>-1</sup> (5.8 ± 2 Tg-N y <sup>-1</sup> )
Bianchi et al. 2012	6.2 ± 3.2 Tg-N y <sup>-1</sup>
Freing et al. 2012	3.1-3.4 ± 0.9 Tg-N y <sup>-1</sup>
Zamora and Oschilies 2014	1.6-11.7 Tg-N y <sup>-1</sup>
Babbin et al. 2015	~4 Tg-N y <sup>-1</sup> from ODZs alone (no global estimate)
Battaglia and Joos 2017	~4.5 Tg-N y <sup>-1</sup> (3.0-6.1 Tg-N y <sup>-1</sup> )
Ji et al. 2018	1.7-4.4 Tg-N y <sup>-1</sup>
Buitenhuis et al. 2018	2.4-2.5 ± 0.8 Tg-N y <sup>-1</sup>
Sun et al. 2021	3-5 Tg-N y <sup>-1</sup>

Uncertainties in reaction mechanisms are also highlighted by studies on genomics and gene expression (e.g., Ulloa et al. 2012, Newell et al. 2013, Jayakumar et al. 2017, Pajares and Ramos 2019), both in recognizing major reaction pathways and determining community composition in varying marine environments. Microbial community structure in coastal environments is very different from that in the open ocean, and differs between the low-oxygen core of ODZs and the region near the oxycline (Sun et al. 2017, Coates and Wyman 2017, Rees et al. 2021).

Overall, the global ocean nitrogen budget remains poorly constrained – especially regarding  $\text{N}_2\text{O}$  as produced by nitrification and denitrification. Currently, the best available global budgets estimate the ocean  $\text{N}_2\text{O}$  source at approximately 2.5-4.3  $\text{Tg N y}^{-1}$  for the decade of 2007-2016 (Figure 3) (Ciais et al. 2013, Tian et al. 2020), although the estimates by various models and observational studies can vary anywhere between approximately 2 to 12  $\text{Tg N y}^{-1}$  (Table 1).

Comparing the estimated 2.5-4.3  $\text{Tg N y}^{-1}$  produced by the ocean to the total sum of natural sources of  $\text{N}_2\text{O}$  (8.0-17.0  $\text{Tg-N y}^{-1}$ ) and anthropogenic sources (4.7-11.4  $\text{Tg-N y}^{-1}$ ) over the same time period (Ciais et al. 2013) reinforces the idea that marine  $\text{N}_2\text{O}$  emissions comprise a sizable portion of the global  $\text{N}_2\text{O}$  budget and should be better defined to project global climate and effects of anthropogenic change (Battaglia and Joos 2018, Bange et al. 2019).

**Figure 3:** Global  $\text{N}_2\text{O}$  budget with sources and sinks (from Tian et al. 2020)

In addition to a dearth of data on  $\text{N}_2\text{O}$  reaction mechanisms, ongoing discoveries force scientists to adapt and update their understanding of the nitrogen cycle itself. As an example, nitrification has historically been attributed to bacterial nitrifiers in oxic environments while denitrification has been attributed to bacterial denitrifiers in anoxic environments. In recent years, however, novel pathways – such as anammox, ammonium oxidation by archaea, and anaerobic nitrogen fixation (Dalsgaard et al. 2005, Könneke et al. 2005, Dekas et al. 2009, Löscher et al. 2012) – have revealed new nitrogen cycling pathways that compound the need for a re-examination of the nitrogen cycle (Thamdrup 2012, Voss et al. 2013). Furthermore, discovery of atypical *nosZ* genes – the genes responsible for nitrous oxide consumption (Figure 1) – existing in environments with unexpectedly high oxygen concentrations has led to scrutiny of established

ideas about oxygen inhibitions of denitrification processes (Sun et al. 2017, 2021, Rees et al. 2021).

These new nitrogen cycling processes affect the ongoing debate over the magnitude of nitrification and denitrification occurring globally, as well as over the comparative strength of regional  $\text{N}_2\text{O}$  production (Thamdrup 2012, Kriest and Oschlies 2015, Ji et al. 2018, Tian et al. 2020). The consumption of nitrogen species to produce  $\text{N}_2\text{O}$  and  $\text{N}_2$  influences nutrient availability and so is directly relevant to ocean productivity. Moreover, the emission of  $\text{N}_2\text{O}$  gas from the ocean's surface provides a substantial portion of global atmospheric concentrations, contributing to the intensifying effects of greenhouse gases.

Yet despite its environmental importance,  $\text{N}_2\text{O}$  is often ignored in both biogeochemical models and sustainable development goals (Kanter et al. 2020). The current lack of data on microbial community structure, reaction rates, and oxygen inhibition impedes quantification of both novel and well-established processes; therefore, this research employs computer models to simulate and investigate possible scenarios over the whole range of pelagic marine environments.

### Research Questions & Scope of Research

The goal of this project is to generate a computer simulation model representing the nitrification and denitrification pathways leading to ocean  $\text{N}_2\text{O}$  production to better identify the key uncertainties that control these reactions. In creating this simulation, the sensitivity of  $\text{N}_2\text{O}$  production rates to environmental conditions are investigated in a portable mathematical model that can be integrated into global Earth System Models to support projections of future ocean  $\text{N}_2\text{O}$  emissions. By isolating these reactions in a controlled virtual environment, the questions and uncertainties concerning  $\text{O}_2$  inhibition of various processes, representations of rate equations, and the relative contribution of each reaction can be better defined. This provides more robust nitrification and denitrification biogeochemical pathway representation, particularly in quantifying the relative contribution of these individual reactions to  $\text{N}_2\text{O}$  production and emissions from the ocean. The computer model is designed to answer the following research questions and ultimately provide a road map of the most important “missing quantities” in our understanding of  $\text{N}_2\text{O}$  dynamics that will need to be improved in future observational studies.

- When parameterizing  $\text{N}_2\text{O}$  production and consumption, what are the key uncertainties and how strongly do these uncertainties affect net  $\text{N}_2\text{O}$  production?
- How do key uncertainties affect how much  $\text{N}_2\text{O}$  production occurs in the oxic ocean compared to the suboxic ocean? In the global ocean, is more  $\text{N}_2\text{O}$  produced by nitrification or denitrification?
- What are the main controls on  $\text{N}_2\text{O}$  production by nitrification and denitrification?
- How do environmental conditions and substrate availability affect the partitioning of  $\text{N}_2\text{O}$  production between nitrification and denitrification?
- What is the relationship between organic matter remineralization, oxygen, and maximum  $\text{N}_2\text{O}$  production in, and at the boundary of, oxygen deficient zones? In oxygen deficient zones, how does the rate of denitrification production of  $\text{N}_2\text{O}$  compare to denitrification consumption of  $\text{N}_2\text{O}$ ?
- How might anthropogenic changes to environmental conditions affect global ocean  $\text{N}_2\text{O}$  production?

The model will answer these questions by constructing a global 3D representation of how net N<sub>2</sub>O production rates and individual production and consumption rates by nitrification and/or denitrification vary in various environments. By maintaining a relatively simple framework, the controlling elements on N<sub>2</sub>O production and consumption rates can be investigated without considering the full spectrum of biogeochemical processes that occur *in situ*. Past models (Babbin et al. 2015, Ji et al. 2018, Sun et al. 2021) have used similar modelling techniques using a steady state framework, which assumes that reaction rates do not change over time. Such models have found success in using this assumption to develop a plausible range of net N<sub>2</sub>O production rates despite known uncertainties in parameters and parameterizations, and as such provide the basis for the model created here. The model developed in this research has an increased level of detail compared to existing steady-state N<sub>2</sub>O production models and models that have been embedded in global 3D ocean models (e.g., Suntharalingam et al. 2000; Zamora and Oschlies 2014, Battaglia and Joos 2018), with a greater biological focus on individual reaction pathways and the influence of a wider range of environmental conditions (temperature, irradiance, substrate availability) on these reactions. This model's novelty arises from its incorporation of a full, global 3D distribution of environmental conditions, allowing investigation into reaction controls and testing of parameters and parameterizations without necessitating the complexity of a complete Earth System Model.

This 3D model is based on a uniform 2° x 2° latitude/longitude grid over 33 depth layers (Locarnini et al. 2010). Five Earth System Models, CanESM5 (Christian et al. 2022), CanESM5-CanOE (Christian et al. 2022), CNRM-ESM2-1 (Séférian et al. 2019), GFDL-ESM4 (Stock et al. 2020), and UKESM1-0-LL (Yool et al. 2021), were also interpolated to this grid. Parameters and parameterizations used in this model will be a combination of the most recent advances in the literature and the most reasonable best-estimates as determined according to model results and sensitivity. These quantities will be evaluated for their validity in relation to global net N<sub>2</sub>O production rates and used to generate a list of uncertain terms that have the strongest influence on global N<sub>2</sub>O production rates, in the hope that it will highlight the more important gaps to be filled. The finalized parameterization of N<sub>2</sub>O production in the ocean is designed to be utilized in the context of future Earth System Models, and so aims for simplicity and adaptability.

As this project focuses on how O<sub>2</sub> concentrations affect N<sub>2</sub>O production pathways, yield, and magnitude by individual processes, particular attention will be paid to regions with ODZs where O<sub>2</sub> may vary sharply over relatively small distances. Partitioning between nitrification and denitrification is known to be one of the greatest sources of uncertainty in N<sub>2</sub>O modelling, and so particular attention is paid to the relative strength of these processes in and around ODZs. By comparing variation of the N<sub>2</sub>O production rates across these regions of disparate O<sub>2</sub> concentrations, the magnitude of control by O<sub>2</sub> on nitrification, denitrification, and remineralization is better elucidated. Investigating the nature of this O<sub>2</sub> control allows for development of more accurate model estimates of how much N<sub>2</sub>O production occurs in oxic waters compared to suboxic waters, and so determine the proportion of N<sub>2</sub>O provided by each in the global total estimates. This is also of particular importance in analyzing the contribution by denitrification production in relation to denitrification consumption, where O<sub>2</sub> concentrations that reach as low as 1-2 μmol-O<sub>2</sub> L<sup>-1</sup> can affect partitioning between N<sub>2</sub>O production or consumption.

N<sub>2</sub>O production rates' relation to O<sub>2</sub> concentrations are established by quantifying multiple processes: the yield of N<sub>2</sub>O from nitrification, the partitioning of denitrification's production and consumption pathways, and the tolerances of denitrification processes to the presence of O<sub>2</sub>. Once the base case scenario for each of these qualities is established, their sensitivity is examined by varying parameters individually and assessing the change in the N<sub>2</sub>O production rates. Production rates' sensitivity to other environmental conditions (temperature, solar irradiance, substrate availability) are similarly determined: observing independent interactions between rates and varying environmental conditions narrows down a reasonable base case, and sensitivity of each reaction to these environmental conditions is explored by changing the representative parameters.

Parameters are altered within a range that is reasonable given available literature data or using best estimates in the scheme of the model if there is little or no available data. In this way, the degree of control by known uncertain qualities can be analyzed to determine the most relevant parameters that need more elucidation in future observational and laboratory research. Best estimates of uncertain parameters are generated by comparing the output global net production rates to past model estimates from literature.

N<sub>2</sub>O concentrations (instead of rates) are not a reliable measure of model credibility as concentrations can not be compared to in situ data without considering ocean circulation and other complexities of ocean biogeochemical cycling. However, a general awareness of the magnitude of concentrations in the ocean and in the model are useful in discerning if regional patterns are comparable. For example, elevated N<sub>2</sub>O production is observed in and around oxygen deficient zones in observational data, which is also represented in this model at the same locations.

In addition to existing environmental conditions, the model's sensitivity to projected environmental conditions as a result of anthropogenic climate change is evaluated using data from Earth System Models: CanESM5 (Christian et al. 2022), CanESM5-CanOE (Christian et al. 2022), CNRM-ESM2-1 (Séférian et al. 2019), GFDL-ESM4 (Stock et al. 2020), and UKESM1-0-LL (Yool et al. 2021). The N<sub>2</sub>O production rates that arise from using these different models as input environmental conditions help project possible changes in N<sub>2</sub>O cycling and N<sub>2</sub>O emitted from the ocean to the atmosphere, and so aid understanding of greenhouse gas emissions in a future ocean with different biogeochemical properties.

## Thesis Outline

The following Methodology section (Section 2.0) will summarize how the computer model was created and how it uses steady state conditions through use of a 'virtual chemostat' to simulate real world N<sub>2</sub>O production and consumption rates. It will also list the relevant inputs to the model and their derivations and detail the source material for data products generated outside the scope of the model. The basic model framework is described in Section 2.1, with process equations and equations for environmental conditions provided in Sections 2.1.1 and 2.1.2, and explanation of relevant data sets in Section 2.1.3. The nature of the steady state model or "virtual chemostat" will be explained in Section 2.2, with Section 2.2.1 describing the model initialization.

The Results section (Section 3.0) will begin with evaluation of the characteristics of global and regional N<sub>2</sub>O production and consumption rates in Section 3.1 and will analyze sensitivity of N<sub>2</sub>O production and consumption rates to oxygen (Section 3.2), remineralization of organic matter (Section 3.3) and to environmental conditions (Section 3.4). An in-depth investigation of how all individual parameters, environmental conditions, and data product inputs affect N<sub>2</sub>O production rates will be presented in Section 3.5, and Section 3.6 will provide projections of N<sub>2</sub>O production and consumption rates in relation to future ocean conditions for O<sub>2</sub>, organic matter, and temperature as generated by five Earth System Models.

The Discussion (Section 4.0) will explain the significance of the uncertain parameters, environmental conditions, and data products that have the greatest influence on N<sub>2</sub>O production in the ocean in Section 4.1 and will evaluate the model validity in relation to past literature in Section 4.2. Model significance and an estimation of potential future effects of climate change on N<sub>2</sub>O production will be discussed in Section 4.3.

The conclusion (Section 5.0) will summarize the scope of the model and its relevance to science and society.

## 2 Methodology

This research uses a computer model as a ‘virtual laboratory’ to investigate how N<sub>2</sub>O production rates can be estimated from mathematical representations of relevant processes and environmental conditions, using observed data and computer simulations. In this section the process equations for reaction pathways of N<sub>2</sub>O production will be described, as well as environmental conditions such as solar irradiance, temperature, oxygen, and substrate concentrations.

### 2.1 Model Description

To simplify the full spectrum of reactions related to N<sub>2</sub>O production and nitrogen cycling, five state variables will be used in representing remineralization, nitrification, and denitrification. These are *oxygen* (O<sub>2</sub>), *detritus* (organic nitrogen – orgN), *ammonium* (NH<sub>4</sub><sup>+</sup>), *nitrate* (NO<sub>3</sub><sup>-</sup>), and *nitrous oxide* (N<sub>2</sub>O). These five state variables are affected by five process equations depicting their rate of change, which are described here and followed by a table of parameter values. Process reactions are represented as rates of change of the state variables in the form  $d[X]/dt$ , where  $[X]$  is the concentration of the state variable and  $d/dt$  is the rate of change.

The state variables, parameters, and equations used to depict relevant N<sub>2</sub>O production processes concern three main reactions: remineralization (by both oxic and denitrification processes), ammonium oxidation (part of the nitrification process that can produce N<sub>2</sub>O), and N<sub>2</sub>O consumption by denitrification. N<sub>2</sub>O production processes are primarily controlled by oxygen availability, but also by first order rate constants, substrate concentration, and environmental conditions such as temperature and irradiance. Parameterizations of environmental conditions will be detailed in the section following the main process equations and table of values.

While it is possible to parameterize these processes with more chemical species and with a wider variety of environmental conditions, the following equations represent the most essential factors known to affect these reactions. Avoiding unnecessary complications allows a deeper investigation into the main controls on N<sub>2</sub>O production and consumption processes.

#### 2.1.1 Process Equations

The equation for the rate of change of the first state variable, detritus ( $D$ ), is depicted in *Equation 1*, detailing how detrital organic matter is remineralized by both oxic and suboxic processes. The partitioning between oxic and suboxic remineralization is represented by  $\Omega$ , which will be described in *Equation 3*.

$$\frac{d}{dt} [D] = -(1 - \Omega)k_{remin}T_g [D] - (\Omega)fNO_{3,remin}k_{remin}T_g [D] \quad (\text{Equation 1})$$

Temperature affects remineralization rates according to the Arrhenius Equation (Burdige and Komada 2011, Laufkötter et al. 2017) using a reference temperature ( $T_{ref}$ ) of 12°C (285.15 K), the activation energy required for remineralization of organic matter ( $E_a = 5.4 \times 10^3 \text{ J mol}^{-1}$ ) (Medlyn et al. 2002, Bunce 2019), and the gas constant ( $R = 8.31447 \text{ J K}^{-1} \text{ mol}^{-1}$ ). The term  $T_g$  describes the Arrhenius equation and the effect temperature has on the remineralization rate (*Equation 2*).

$$T_g = e^{\frac{-E_a}{R} \left( \frac{1}{T} - \frac{1}{T_{ref}} \right)} \quad (\text{Equation 2})$$

Lower temperatures decrease the reaction rate of remineralization processes while higher temperatures increase the reaction rate (Figure 4). Most of the world's ocean below the euphotic zone (100 m) is cold, with a mean temperature of approximately 5°C (Locarnini et al. 2018). The interactions between the spatial patterns of temperature in relation to spatial patterns of organic matter supply can alter the magnitude of remineralization rates throughout the global ocean (Rahmstorf 2002, Burdige and Komada 2011, Laufkötter et al. 2017).

**Figure 4:** Effect of temperature on remineralization using the Arrhenius function ( $T_g$ )

As most of the world's ocean lies around the mean of 5°C, the average effect  $T_g$  has on remineralization rates is decreasing the base rate by up to 50-60% relative to the reference temperature of 12°C, although as mentioned above this is subject to small changes. The higher temperature range of 20-28°C rarely occurs below 100 m, so it is rare that the  $T_g$  exceeds 2 as shown in Figure 4. As this model does not include depths shallower than 100 m, the focus is on cooler temperatures.

In *Equation 1*, detritus is only consumed as this model does not include processes that occur in the euphotic zone that generate organic matter. Instead, organic matter produced at the surface that has reached depths past 100 m is consumed through oxic remineralization ( $1-\Omega$ ) and suboxic remineralization ( $\Omega$ ), which is the first step of denitrification (*Equation 3*). Both oxic and

suboxic remineralization are affected by temperature according to  $T_g$  and a remineralization rate constant,  $k_{remin} = 0.25 \text{ d}^{-1}$ , common to both.

$$\Omega = \left( \frac{thr_{O_2, remin} - \min\{[O_2], thr_{O_2, remin}\}}{thr_{O_2, remin}} \right)^c \quad (\text{Equation 3})$$

Equation 3 details the partitioning between oxic and suboxic remineralization according to  $O_2$  concentrations, where  $\Omega$  represents the fraction of suboxic remineralization and  $(1-\Omega)$  represents the fraction of oxic remineralization. The  $O_2$  threshold where suboxic remineralization begins,  $thr_{O_2}$ , is set at  $6 \mu\text{mol-O}_2 \text{ L}^{-1}$  – a median of estimates from  $2\text{-}10 \mu\text{mol-O}_2 \text{ L}^{-1}$  (Codispoti et al. 2001, Devol et al. 2008, Dalsgaard et al. 2014) - and the exponent  $c$  controls how quickly oxic remineralization declines and suboxic remineralization increases with decreasing  $O_2$ . For the base case scenario of the model,  $c = 3$ , so that  $\Omega$  takes the shape depicted in Figure 5 (red) and  $1-\Omega$  takes the shape depicted in blue.

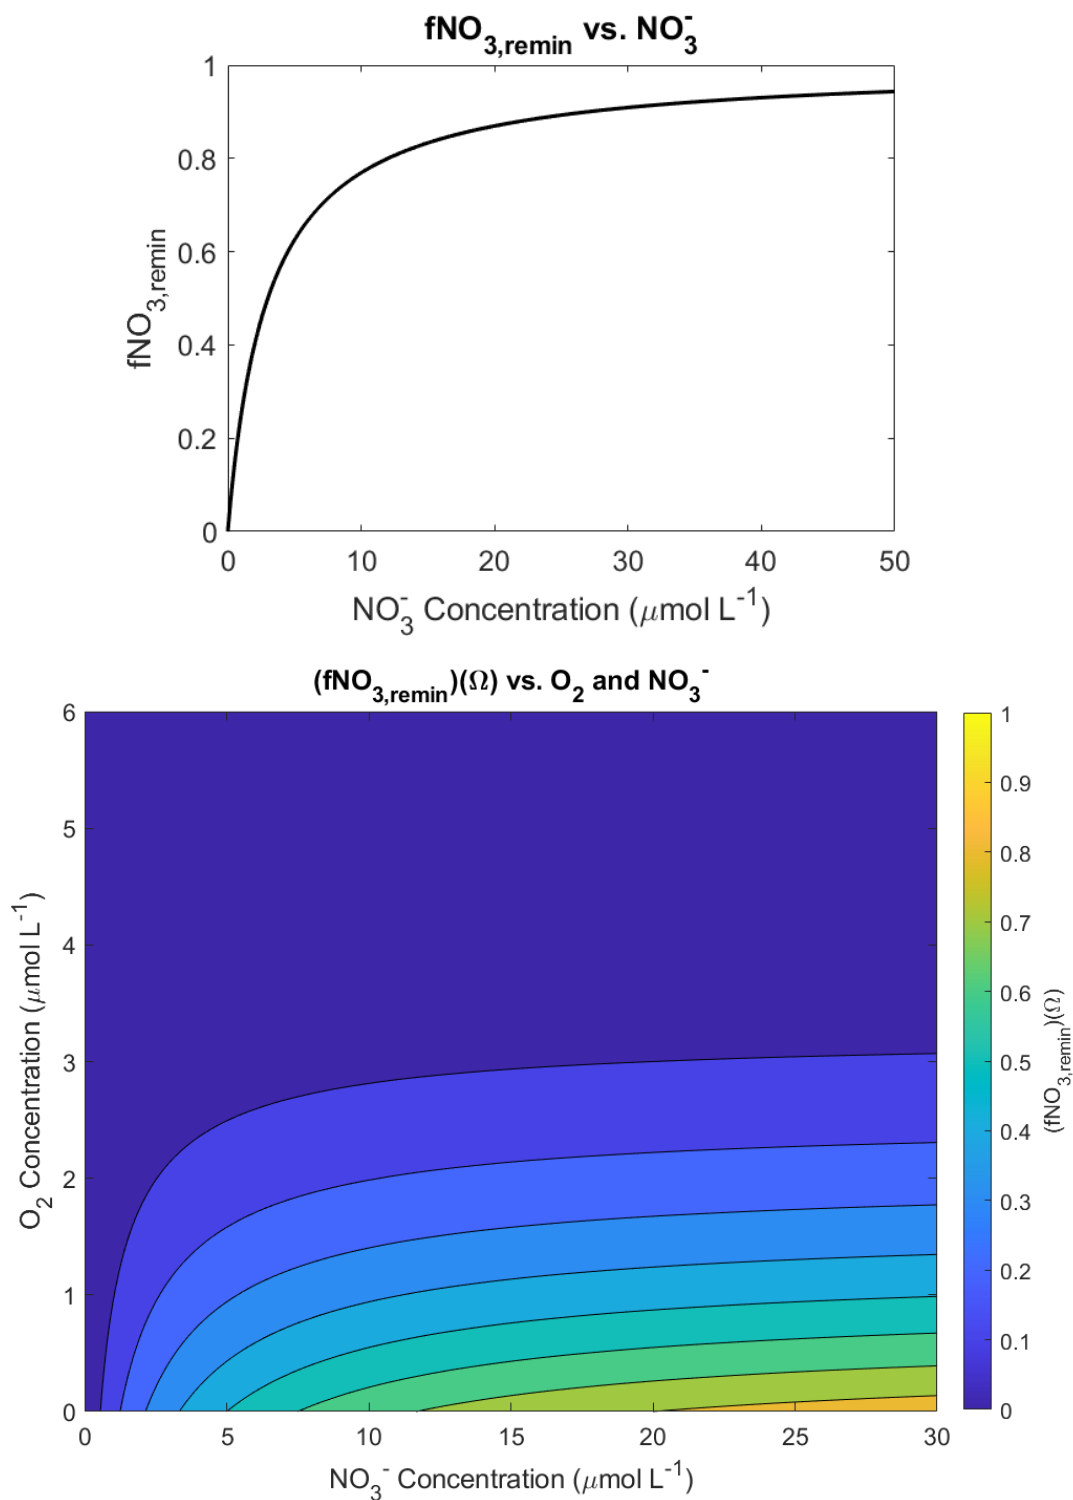

**Figure 5:** Fraction of suboxic remineralization,  $\Omega$  (red), and oxic remineralization,  $1-\Omega$  (blue), at  $O_2$  concentrations in the suboxic range from  $0\text{-}6 \mu\text{mol-O}_2 \text{ L}^{-1}$ .

Figure 5 shows how the portion of oxic and suboxic remineralization changes gradually according to  $O_2$  and the exponent  $c$ . While suboxic remineralization can only begin to occur starting at  $O_2 \leq 6 \mu\text{mol-O}_2 \text{ L}^{-1}$ , oxic remineralization still occurs in the suboxic  $O_2$  range from  $0\text{-}6 \mu\text{mol-O}_2 \text{ L}^{-1}$  though it decreases rapidly as  $O_2$  approaches zero. The parameter  $c$  was chosen to mimic the shape of the  $\Omega$  curve of increasing denitrification with decreasing  $O_2$  according to Devol (1978) and Dalsgaard et al. (2012, 2014).

Suboxic remineralization ( $\Omega$ ) is also controlled by the term  $fNO_{3,rem}$  (*Equation 4*) according to  $NO_3^-$  concentrations – this is because  $NO_3^-$  is used as the electron acceptor in suboxic remineralization, instead of  $O_2$  as the electron acceptor in oxic remineralization. If  $NO_3^-$  concentrations are very low, then the rate of suboxic remineralization will be restricted according to a Michaelis-Menten-style curve using a half-saturation constant  $K_{NO_3,rem} = 5 \mu\text{mol-}NO_3^-$ .

$$fNO_{3,rem} = \frac{[NO_3^-]}{[NO_3^-] + K_{NO_3,rem}} \quad (\text{Equation 4})$$

The Michaelis Menten curve of  $fNO_{3,rem}$  versus  $NO_3^-$  in *Equation 4* is depicted in Figure 6 (top), and the proportion of suboxic remineralization in relation to  $NO_3^-$  and  $O_2$  is visualized in Figure 6 (bottom) by multiplying  $fNO_{3,rem}$  and  $\Omega$ .

**Figure 6:**  $fNO_{3,rem}$  versus  $NO_3^-$  (top), and relationship of  $(fNO_{3,rem})(\Omega)$ ,  $NO_3^-$ , and  $O_2$  (bottom).

In the top panel of Figure 6,  $fNO_{3,rem}$  decreases with  $NO_3^-$ , especially below concentrations of approximately  $10 \mu\text{mol-NO}_3^- \text{ L}^{-1}$ . In the bottom panel, there is a greater change of  $\Omega$  along the vertical  $O_2$  axis rather than the horizontal  $NO_3^-$  axis. This is because the rate of suboxic remineralization (denitrification) is more strongly regulated by  $O_2$  than by  $NO_3^-$ .

The second main process equation concerns the rate of change of ammonium,  $NH_4^+$ , and is described by *Equation 5*.

$$\begin{aligned} \frac{d}{dt}[NH_4^+] = & (1 - \Omega)k_{remin}T_g[D] + (\Omega)fNO_{3,remin}k_{remin}T_g[D] \\ & - (\gamma)fO_{2,AmOx}k_{AmOx}[NH_4^+] \left( \frac{E_x}{E_x + E_z} \right) \\ & - (1 - \gamma)fO_{2,AmOx}k_{AmOx}[NH_4^+] \left( \frac{E_x}{E_x + E_z} \right) \end{aligned}$$

(*Equation 5*)

*Equation 5* details how  $NH_4^+$  is both produced by remineralization of detritus (first two terms) and consumed by ammonium oxidation through nitrification (second two terms). Nitrification is a multiple-step process that involves  $NH_2OH$  and  $NO_2^-$  as intermediates, but for the purposes of this model it is being represented as a single step reaction. The remineralization terms are the same as those in *Equation 1*.

The nitrification terms consume  $NH_4^+$  to produce both  $NO_3^-$  and  $N_2O$  as a by-product using the partitioning term  $\gamma$ .  $\gamma$  represents the yield of  $N_2O$  from ammonium oxidation, while  $1-\gamma$  represents the yield of  $NO_3^-$  (*Equation 6*).

$$\gamma = 0.01 \left( \frac{a}{[O_2]} + b \right)$$

(*Equation 6*)

*Equation 6* uses  $O_2$  concentrations to determine the yield of  $N_2O$  in relation to  $NO_3^-$ , where  $a = 0.2 \mu\text{mol-O}_2 \text{ L}^{-1}$  and  $b = 0.08$  (Ji et al., 2018). This equation was first used by Nevison et al. (2003) and was later revised by Ji et al. (2015, 2018) to better represent in-situ observational yields. Figure 7 provides a visualization of how the percent yield of nitrification changes with  $O_2$ ; note that the equation for  $\gamma$  that is used within the model includes multiplication by 0.01, while the figure below removes this 0.01 to depict yield as a percent.

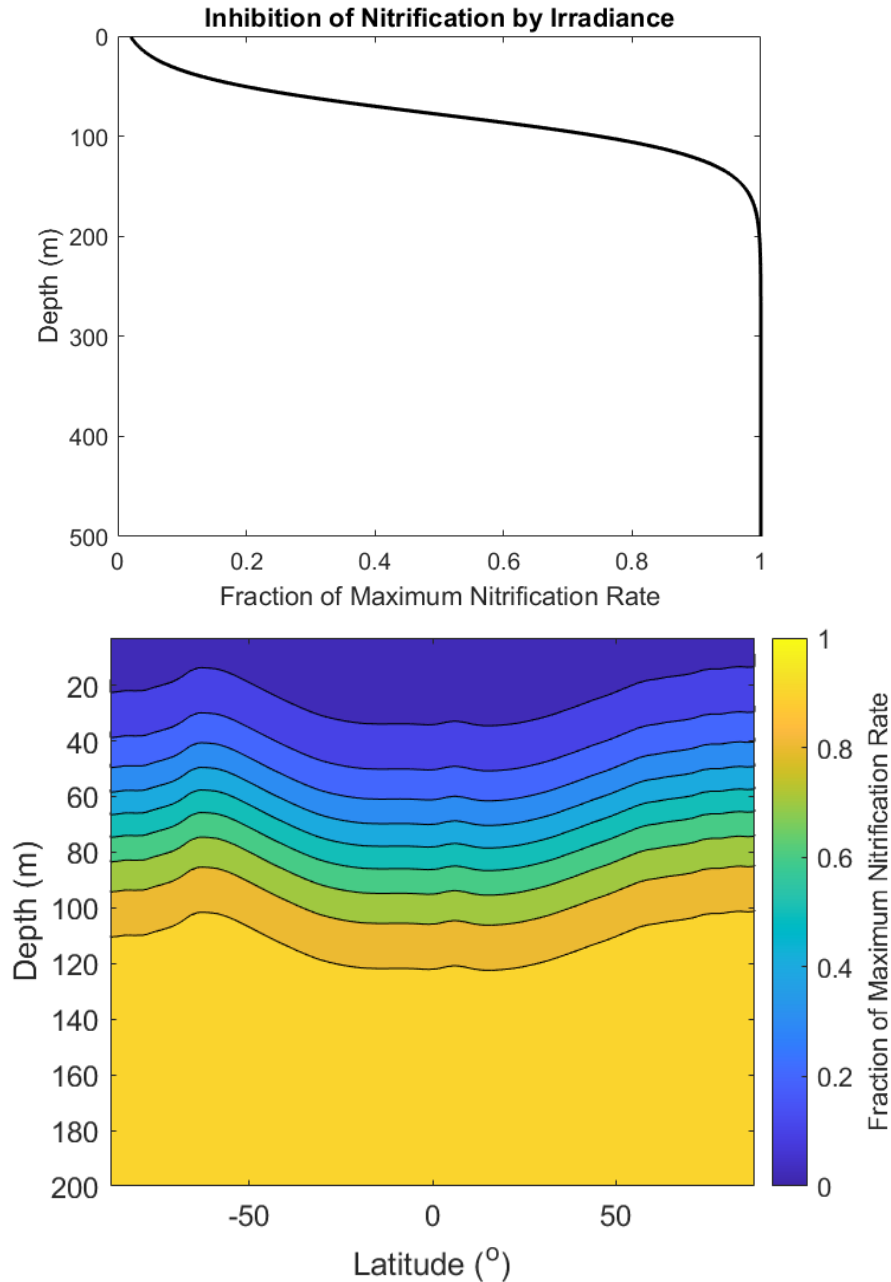

**Figure 7:** Percent yield of N<sub>2</sub>O from nitrification versus O<sub>2</sub> concentrations.

In Figure 7, the percent yield of N<sub>2</sub>O (vertical axis) is very low at higher O<sub>2</sub> concentrations but increases exponentially as O<sub>2</sub> reaches suboxic and anoxic concentrations. Because of this, the yield of N<sub>2</sub>O from nitrification in oxic waters is very low (approx. 0.04%) despite higher overall nitrification rates, while the yield of N<sub>2</sub>O in suboxic waters is higher while nitrification rates become quite small.

This relationship between yield of N<sub>2</sub>O and O<sub>2</sub> is integral to understanding how much N<sub>2</sub>O is produced in the oxygenated waters, which comprise most of the global ocean, versus the suboxic waters that are mostly only present in ODZs. Despite most of the world's seawater being oxygenated and therefore capable of N<sub>2</sub>O production through nitrification, the yield of N<sub>2</sub>O is often so low that very little of the global total may be produced through this pathway.

In addition to  $\gamma$ , the nitrification rate is controlled by a rate constant,  $k_{AmOx} = 0.8 \text{ d}^{-1}$ , a solar irradiance inhibition factor,  $E_x/(E_x+E_z)$ , and O<sub>2</sub> according to  $f_{O_2,AmOx}$ . Solar irradiance affects nitrification rates – light inhibits the nitrification process, such that increased irradiance will result in lower nitrification rate. Since the model does not include the euphotic zone, the

influence of solar irradiance on nitrification is small but not negligible. The light inhibition term,  $E_x/(E_x+E_z)$ , requires a depth-dependent irradiance,  $E_z$ .  $E_z$  and its parameterization is discussed further in Section 2.1.2. The effect of irradiance on nitrification at various depths and latitudes is depicted in Figure 8, with  $E_z$  (irradiance at depth) discussed further in Section 2.1.2 (Equation 11).

**Figure 8:** Inhibition of nitrification by solar irradiance. Top panel shows a one-dimensional depth profile using annually and globally averaged surface solar irradiance ( $E_0$ ), bottom panel uses annually averaged zonal mean surface solar irradiance across various latitudes.

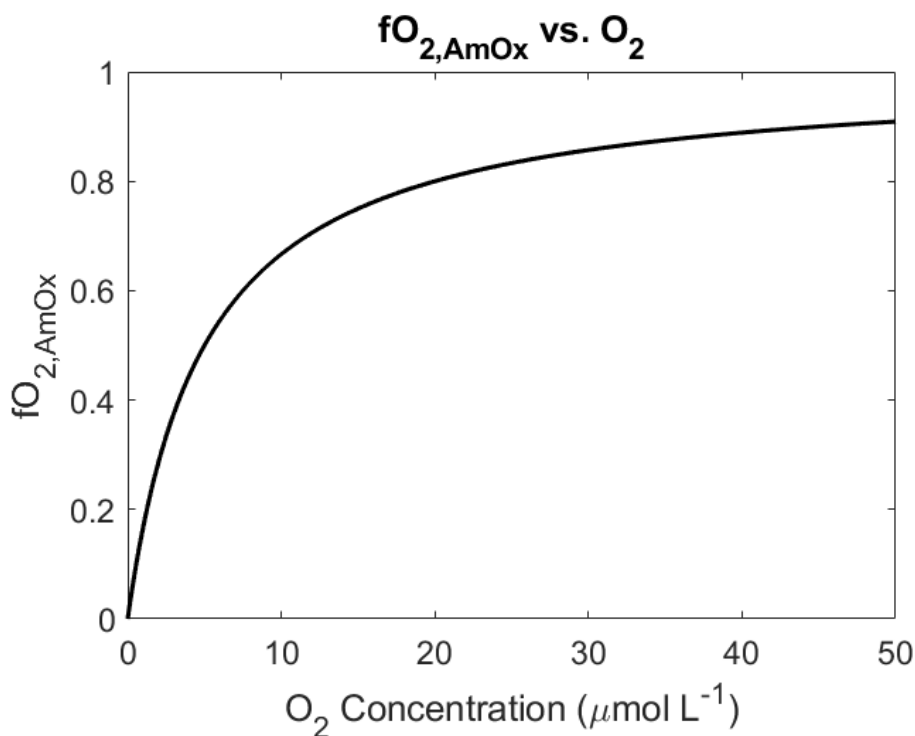

In the real world, the euphotic zone depth is correlated with the light attenuation coefficient  $a_c$ ; however, within the scope of this model a constant  $a_c$  and euphotic zone depth are assumed. This

means that the inhibitory effect of solar irradiance does not reach far past the set depth of the euphotic zone (100 m) and so does not have a strong influence on nitrification except at depths of approx. 100-125 m (Figure 8). In the real world, light attenuation and euphotic zone depth vary strongly by location across the globe; however, for the purposes of N<sub>2</sub>O production via nitrification such a simplification is expected to have very little effect on results (see Sections 3.4.2, 3.4.3).

$f_{O_2,AmOx}$  is another Michaelis-Menten-style parameter that limits the rate of nitrification as O<sub>2</sub> decreases. While the rate of ammonium oxidation is reduced with decreasing O<sub>2</sub> (Equation 7), the yield of N<sub>2</sub>O (in relation to NO<sub>3</sub><sup>-</sup>) is *increased* with decreasing O<sub>2</sub> (Equation 6). This unique relationship with O<sub>2</sub> is what necessitates two individual O<sub>2</sub>-dependent parameterizations:  $f_{O_2,AmOx}$  and  $\gamma$ .

$$f_{O_2,AmOx} = \frac{[O_2]}{[O_2] + K_{O_2,AmOx}} \quad (\text{Equation 7})$$

$f_{O_2,AmOx}$  uses O<sub>2</sub> concentrations and a half-saturation constant,  $K_{O_2,AmOx} = 5 \mu\text{mol-O}_2 \text{ L}^{-1}$ , to limit nitrification rates with decreasing O<sub>2</sub>. This differs from  $\gamma$ , which does not affect the rate of nitrification itself but the yield of N<sub>2</sub>O from nitrification.  $f_{O_2,AmOx}$  is illustrated in Figure 9 in relation to O<sub>2</sub> concentration.

**Figure 9:**  $f_{O_2,AmOx}$  versus O<sub>2</sub>.  $f_{O_2,AmOx}$  decreases the rate of nitrification as O<sub>2</sub> decreases, especially below approximately 10 μmol-O<sub>2</sub> L<sup>-1</sup>.

Similar to the depiction of  $f_{NO_3,remn}$  in Figure 6, Figure 9 shows how  $f_{O_2,AmOx}$  follows a Michaelis-Menten curve, decreasing the rate of nitrification at low O<sub>2</sub> concentration.

The third main process equation is the rate of change of  $\text{NO}_3^-$ , where  $\text{NO}_3^-$  is increased through nitrification and consumed through denitrification production of  $\text{N}_2\text{O}$  (suboxic remineralization) (*Equation 8*).

$$\frac{d}{dt}[\text{NO}_3^-] = (1 - \gamma)fO_{2,AmOx}k_{AmOx}[\text{NH}_4^+] \left( \frac{E_x}{E_x + E_z} \right) - (\Omega)fNO_{3,remin}k_{remin}T_gR_{NO3:orgN}[D] \quad (\text{Equation 8})$$

$\text{NO}_3^-$  is produced by nitrification (first term) and consumed by suboxic remineralization, or denitrification (second term). In the first term,  $1-\gamma$  is the yield of nitrification to  $\text{NO}_3^-$  instead of  $\text{N}_2\text{O}$ , and is identical to the last term in the  $\text{NH}_4^+$  process equation (*Equation 5*). The second term is similar to the previous representations of remineralization with one notable change – a Redfield ratio,  $R_{NO3:orgN}$ .  $R_{NO3:orgN}$  is used to convert from moles of detritus (orgN) consumed to the proportionate amount of moles of  $\text{NO}_3^-$ , where  $R_{NO3:orgN} = (106 \text{ mol C} : 16 \text{ mol N})(4 \text{ mol } \text{NO}_3^- : 5 \text{ mol C}) = 5.3$  (Redfield 1958, Froelich et al. 1979).

The next main process equation concerns  $\text{O}_2$  and is described in *Equation 9*.  $\text{O}_2$  is only consumed in this model for the same reason detritus is only consumed – the model only concerns the regions below the euphotic zone, and so sources of  $\text{O}_2$  like photosynthesis or gas exchange with the atmosphere are not considered.

$$\frac{d}{dt}[\text{O}_2] = -(\gamma)fO_{2,AmOx}k_{AmOx}[\text{NH}_4^+] \left( \frac{E_x}{E_x + E_z} \right) - 2(1 - \gamma)fO_{2,AmOx}k_{AmOx}[\text{NH}_4^+] \left( \frac{E_x}{E_x + E_z} \right) - (1 - \Omega)k_{remin}T_gR_{O2:orgN}[D] \quad (\text{Equation 9})$$

The rate of consumption of  $\text{O}_2$  is governed by three terms – the first term is consumption by ammonium oxidation to produce  $\text{N}_2\text{O}$  ( $\gamma$ ), the second term is consumption by ammonium oxidation to produce  $\text{NO}_3^-$  ( $1-\gamma$ ), and the third term is consumption of detritus by oxic respiration ( $\Omega$ ). 2 moles of  $\text{O}_2$  are required to oxidize the 2 moles of  $\text{NH}_4^+$  used to produce 1 mole of  $\text{N}_2\text{O}$ . Similarly, 2 moles of  $\text{O}_2$  are consumed when producing 1 mol of  $\text{NO}_3^-$  by nitrification. The third term includes the Redfield ratio,  $R_{O2:orgN} = (106 \text{ mol } \text{O}_2 : 16 \text{ mol N})$ , that refers to the moles of  $\text{O}_2$  needed to remineralize 1 mole of organic nitrogen. This  $R_{O2:orgN}$  is a simplification, as deviations from the 106:16 ratio can arise depending on the area of study and the community composition of phytoplankton. Such nuances were not taken into consideration for this project, and so the  $R_{O2:orgN}$  is smaller than the 163:22 ratio posited by more modern studies (Martiny et al. 2014).

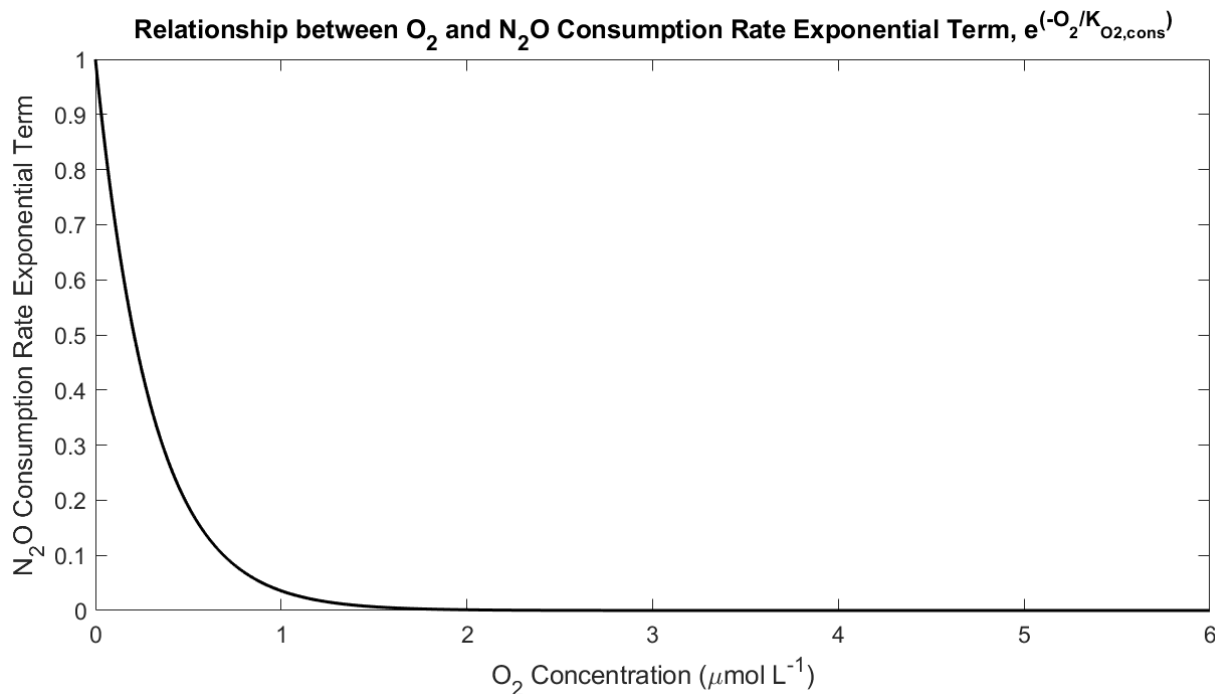

The final process equation is for the rate of change of  $\text{N}_2\text{O}$  and is the primary focus of the model results (*Equation 10*).

$$\begin{aligned} \frac{d}{dt}[\text{N}_2\text{O}] = & 0.5(\gamma)fO_{2,AmOx}k_{AmOx}[\text{NH}_4^+] \left( \frac{E_x}{E_x + E_z} \right) \\ & + 0.5(\Omega)fNO_{3,remin}k_{remin}T_gR_{NO3:orgN}[D] \\ & - k_{cons}[\text{N}_2\text{O}]e^{\left( -\frac{[\text{O}_2]}{K_{O2,cons}} \right)} \end{aligned} \quad (\text{Equation 10})$$

*Equation 10* contains three terms: production of  $\text{N}_2\text{O}$  as a by-product from nitrification, production of  $\text{N}_2\text{O}$  as an intermediate in denitrification (suboxic remineralization), and

consumption of  $\text{N}_2\text{O}$  as the final step of denitrification. The first and second terms are multiplied by 0.5 to reflect that 0.5 moles of  $\text{N}_2\text{O}$  are produced by oxidation of 1 mol of  $\text{NH}_4^+$  through nitrification or by remineralization of detritus using 1 mol of  $\text{NO}_3^-$ .

The last term detailing  $\text{N}_2\text{O}$  consumption by denitrification uses the  $\text{N}_2\text{O}$  produced by both nitrification and denitrification as a substrate, a rate constant ( $k_{cons} = 0.8 \text{ d}^{-1}$ ), and an exponential term that is controlled by  $\text{O}_2$  and an  $\text{O}_2$  inhibition factor,  $K_{\text{O}_2,cons} = 0.3 \text{ } \mu\text{mol-O}_2 \text{ L}^{-1}$  (Dalsgaard et al. 2014; Babbin et al. 2015). This consumption term is illustrated in Figure 10, which shows how  $\text{O}_2$  inhibits consumption of  $\text{N}_2\text{O}$  even at very low  $\text{O}_2$  concentrations.

**Figure 10:** Relative  $\text{N}_2\text{O}$  consumption rate vs.  $\text{O}_2$  concentration.

While the  $\text{O}_2$  inhibition factor,  $K_{\text{O}_2,cons}$ , is set at  $0.3 \text{ } \mu\text{mol-O}_2 \text{ L}^{-1}$ , the exponential nature of the  $\text{N}_2\text{O}$  consumption term is such that  $\text{N}_2\text{O}$  is consumed up to  $\text{O}_2$  concentrations of approximately  $1.5 \text{ } \mu\text{mol-O}_2 \text{ L}^{-1}$ . In this way,  $K_{\text{O}_2,cons}$  is different than the  $thr_{\text{O}_2}$  for suboxic and oxic remineralization in  $\Omega$  (Equation 3) as it isn't a strict threshold but a limiting term.

Table 2 details the model parameter values.

**Table 2:** Table of Parameters for Model Process Equations

Name	Label	Value	Reference	Level of Confidence
Nitrification dependence on O <sub>2</sub> half saturation constant	K <sub>O<sub>2</sub>,AmOx</sub>	5 μmol-O <sub>2</sub> L <sup>-1</sup>	Martens-Habbena et al. 2009, Babbin et al. 2015	Medium
Suboxic Remineralization dependence on NO <sub>3</sub> <sup>-</sup> half saturation constant	K <sub>NO<sub>3</sub>,remin</sub>	5 μmol-NO <sub>3</sub> L <sup>-1</sup>	Babbin et al. 2015	Medium

### 2.1.2 Environmental Conditions

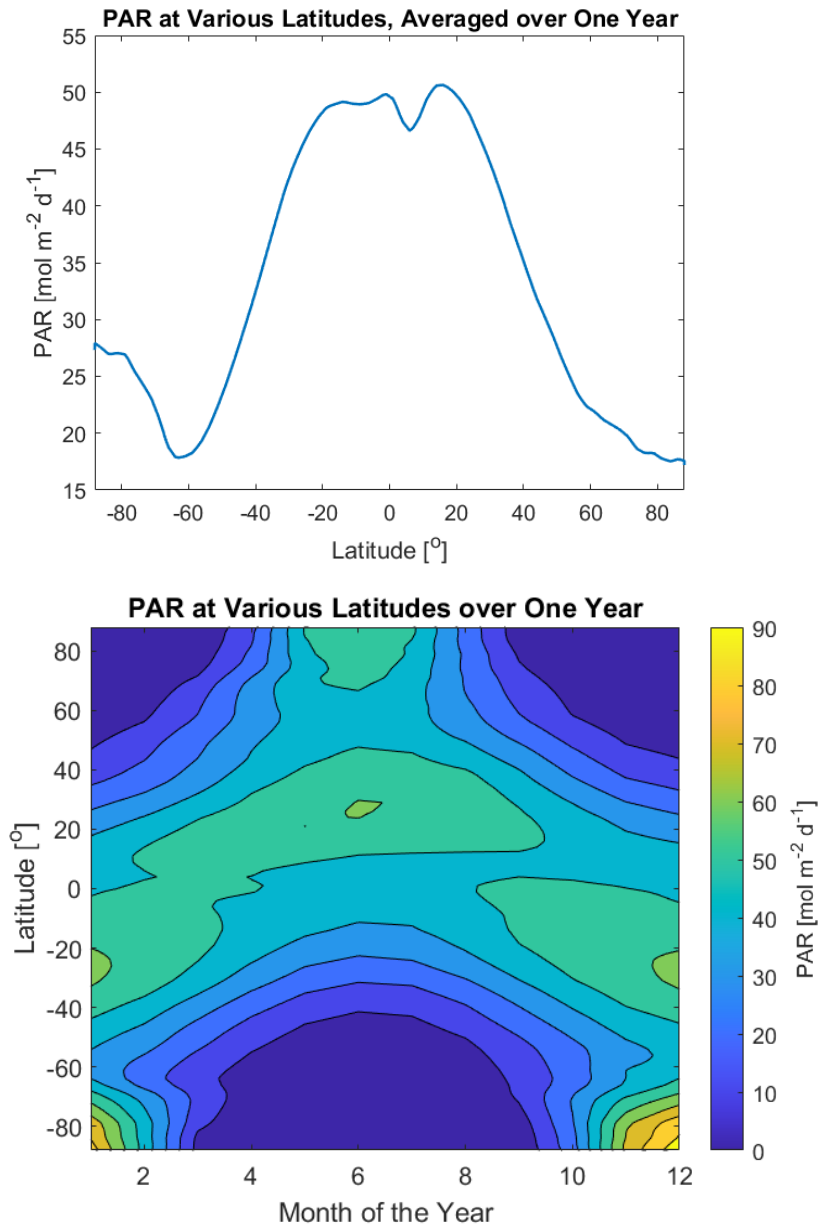

In addition to the process equations described above, there are also environmental conditions that influence the state variables' rates of change. Namely, temperature,  $T$ , which influences remineralization rates, and solar irradiance. Also relevant is how detritus (D) concentrations are generated and input to the system. The source data for detritus uses the flux of particulate carbon exported from the euphotic zone from Earth System Model simulations, and so the parameterization for how exported organic matter is attenuated with depth will affect detritus concentrations.

As mentioned above, the effect of solar irradiance on nitrification is described using  $E_x/(E_x+E_z)$ , where  $E_z$  is calculated from surface solar irradiance,  $E_0$ , and attenuated exponentially with depth ( $z$ ) according to a light attenuation coefficient,  $a_c = 0.05 \text{ m}^{-1}$  (Equation 11) (Arst et al. 1997).

$$E_z = E_0 e^{-a_c z}$$

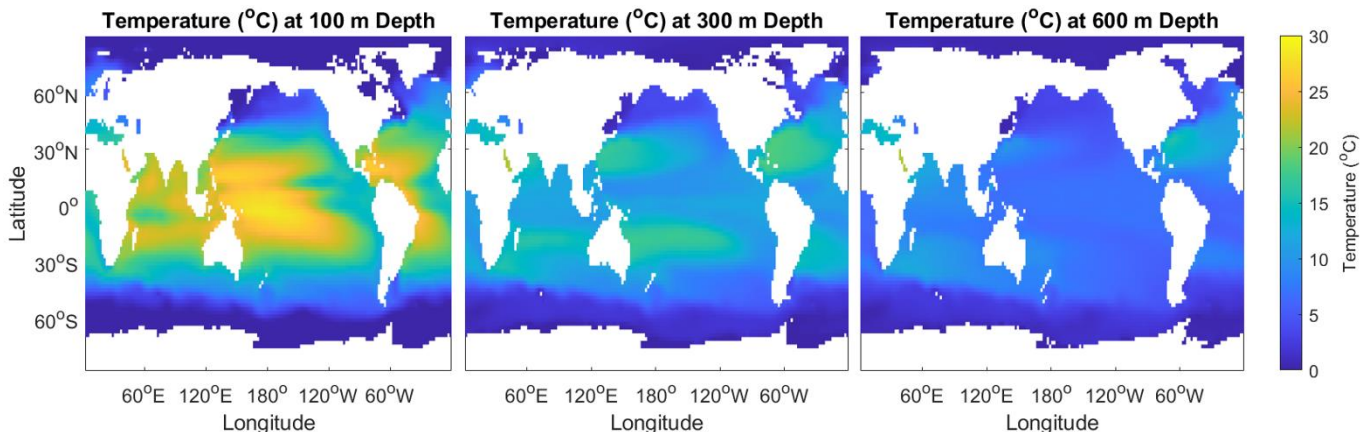

(Equation 11)

To relate surface solar irradiance,  $E_0$ , to biological processes, PAR (Photosynthetically Active Radiation:  $\text{W m}^{-2}$  or  $\text{mol m}^{-2} \text{ d}^{-1}$ ) is often used to represent light energy at the ocean's surface in terms of the wavelengths of light energy that are accessible to photosynthetic organisms (Hall and Rao 1999). The PAR fraction of total surface solar irradiance is set at 0.5 (Kirk 1994). Nitrification rates are limited by light, but how much of this is actual inhibition of the process and how much is indirect (due to competition with phytoplankton with ammonium) is not well understood (Smith et al. 2014). PAR is representative of the wavelengths that penetrate the depths where nitrification occurs, and so using this fraction of total irradiance helps simulate how certain wavelengths of light are most responsible for nitrification rate limitation. Surface PAR is depicted in Figure 11, where the top image shows annually averaged PAR at various latitudes and the bottom image shows temporal variations in PAR at various latitudes.

**Figure 11:** Surface PAR across varying latitudes. Top figure depicts annual averages, while bottom figure depicts monthly variations in PAR over the course of one year. Data from ISCCP (Bishop et al. 1997).

Temperature affects remineralization according to the Arrhenius Equation ( $T_g$ ) (Equation 2), and while spatial variations in temperature are only strong in shallow waters, the circulation of water masses can also cause temperature differences at depth (Figure 12).

**Figure 12:** Regional variations in annual mean temperature at depths of 100 m (left), 300 m (middle), and 600 m (right). Data from World Ocean Atlas (Locarnini et al. 2018).

The temperature variation at 100 m is much greater than at 600 m or more (Figure 12), so the effect of temperature on remineralization will be more substantial in shallower waters.

The attenuation of organic matter flux with depth is a strong control on the remineralization rates that affect all  $N_2O$  production and consumption mechanisms. Detritus flux from the euphotic zone at 100 m is attenuated exponentially according to *Equation 12* to calculate detritus flux at depth ( $F_z$ ) (Marsay et al. 2015).  $F_{eu}$  is the flux of detrital organic matter (orgN) from the euphotic zone,  $\alpha_{RLS} = 0.003 \text{ m}^{-1}$  is the inverse remineralization length scale,  $z$  is depth (m), and  $z_{eu}$  is the euphotic zone depth (100 m).

$$F_z = F_{eu} e^{-\alpha_{RLS} (z - z_{eu})}$$

(Equation 12)

**Figure 13:** Detritus flux ( $F_z$ ) with depth using export from the euphotic zone ( $F_{eu}$ ) and an inverse remineralization length scale ( $a_c$ ) of  $0.003 \text{ m}^{-1}$

The shape of the attenuation curve dictates how much detritus is input into the model at a specific depth, reflecting decreasing concentrations of organic nitrogen with depth (Figure 13). Modelling the availability of organic matter in the ocean is complex and involves many additional parameterizations that are not represented in this model for the sake of simplicity. Including the flux attenuation with depth according to a constant remineralization length scale permits at least a preliminary investigation into how detrital availability affects related  $\text{N}_2\text{O}$  production and consumption processes.

Table 3 provides a list of the sources and conversion factors used for generating input of environmental conditions.

**Table 3:** Environmental Conditions

Name	Label	Value	Units	Reference	Level of Confidence
Light Attenuation coefficient	$a_c$	0.05	$m^{-1}$	Austin and Petzold 1981	Medium
Irradiance at surface	$E_0$	-	$mol\ m^{-2}\ d^{-1}$	Bishop et al. 1997	High
PAR fraction of total surface solar irradiance	-	0.5	-	Kirk 1994	High
Detritus Flux from Euphotic Zone (100 m)	$F_{eu}$	-	$mol-N\ m^{-2}\ d^{-1}$	CMIP6 models (see text) global totals normalized to estimates by Resplandy et al. 2019, Nowicki et al. 2022	Medium
Inverse Remineralization Length Scale	$\alpha_{RLS}$	0.003	$m^{-1}$	Marsay et al. 2014	Medium
Temperature	T	-	K	Locarnini et al. 2018	High
Oxygen	$O_2$	-	$\mu mol-O_2\ L^{-1}$	Garcia et al. 2018a	Low (suboxic)/Medium (oxic)
Nitrate	$NO_3^-$	-	$\mu mol-NO_3^- L^{-1}$	Garcia et al. 2018b	Medium

### 2.1.3 Data Sets

A series of data sets were used as inputs into this model for temperature, solar irradiance,  $O_2$ ,  $NO_3^-$ , and detritus (in the form of EPC – export of particulate carbon from the euphotic zone). The data are gridded on a  $2 \times 2^\circ$  latitude/longitude using 33 depth layers to generate 3D global output of net  $N_2O$  production rates, as well as the individual contributions by nitrification  $N_2O$  production, denitrification  $N_2O$  production, and denitrification  $N_2O$  consumption. The vertical levels are those used in earlier (through 2009) versions of the World Ocean Atlas (e.g., Locarnini et al. 2010).

The 2018 World Ocean Atlas (Locarnini et al. 2018, Garcia et al. 2018a, 2018b) provides temperature as well as  $NO_3^-$  and  $O_2$  data products (monthly climatology) in the base case scenario, while model-generated temperature,  $O_2$ , and EPC are used in sensitivity analyses. In addition to the  $O_2$  data products provided by the World Ocean Atlas,  $O_2$  data products collated by Kwiecinski and Babbín (2021) are also used. The Kwiecinski and Babbín  $O_2$  data is not gridded, but rather consists of a set of individual profiles (see below Section 3.2).  $O_2$  data is adjusted using a correction scheme by Bianchi et al. (2012), which is discussed further in Section 3.2.

Surface solar irradiance data are taken from the International Satellite Cloud Climatology Project (ISCCP) data set (Bishop et al. 1997) and gridded at the same  $2 \times 2^\circ$  resolution. To generate input detritus concentrations, EPC (export production of carbon at 100 m) was taken from Earth System Model simulations using CanESM5 and CanESM5-CanOE (Christian et al. 2022), CNRM-ESM2-1 (Séférián et al. 2019), GFDL-ESM4 (Stock et al. 2020), and UKESM1-0-LL (Yool et al. 2021), with CanESM5-CanOE as the base case. All of the EPC data products are interpolated to the same grid resolution as the World Ocean Atlas and ISCCP data, and the detrital organic matter is translated from units of carbon to units of nitrogen using the same Redfield ratio as for  $O_2$  (see Table 2) All ESM data for present climate are climatologies of the years 1986-2005 of the CMIP6 historical experiment and for future climate years 2081-2100 of the ssp585 experiment (Eyring et al. 2016).

## 2.2 Chemostat: A Virtual Laboratory

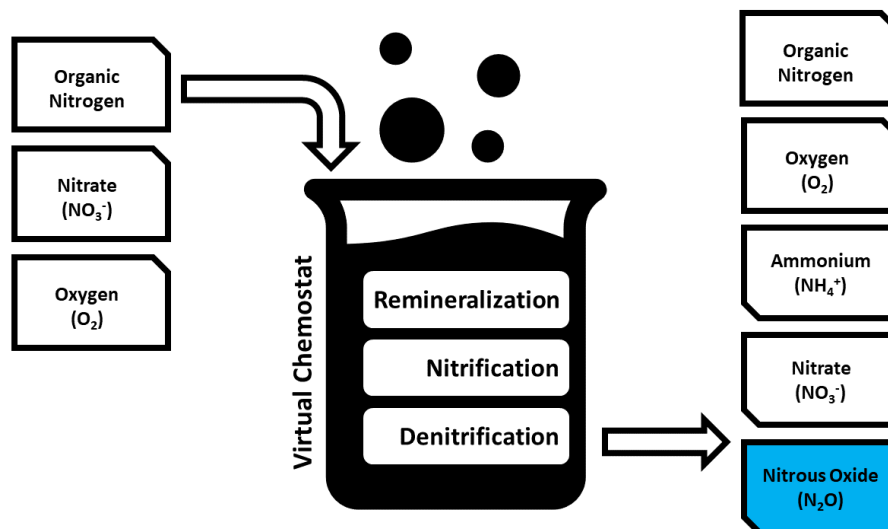

A *virtual chemostat* was created to simulate the above biogeochemical processes. A chemostat is essentially a bioreactor that maintains chemical composition at a controlled level – influent is continuously added and effluent removed at a fixed rate until a constant chemical composition is obtained. A useful metaphor is a beaker filled with active bacterial cultures capable of a known set of chemical reactions. Initially, reactants are added to the beaker to undergo these reactions and be converted into products, with some reactants remaining as ‘leftovers’ in the effluent (Figure 14). When there is no change in output concentrations of the state variables, steady state conditions are met. For the base case scenario of the model (using the parameterizations and constants listed above), the model takes about 40 days to reach steady state.

To generate these steady state conditions, each  $d[X]/dt$  process equation is appended with an additional dilution term as represented by *Equation 13*. The dilution term takes the input concentration of the state variable,  $[X]_{in}$ , and subtracts the steady state concentration at each daily time step,  $[X]$ , then multiplies this by the dilution rate:  $DR([X]_{in} - [X])$ . Source and sink terms refer to those presented in *Equations 1, 5, 8-10*.

$$\frac{d[X]}{dt} = Source_x - Sink_x + DR([X]_{in} - [X]) = 0$$

(Equation 13)

The chemostat can then be applied to a global 3D framework by running the experiment at every grid point on a global 3D grid. The model uses a uniform  $2 \times 2^\circ$  resolution grid with 33 depth levels that range up to 6000 m. There is no physical movement of water or solutes between grid points. As mentioned previously, depths shallower than 100 m are not included because the reactions most relevant to  $N_2O$  occur below the euphotic zone.

**Figure 14:** A schematic of the chemostat, illustrating input and output variables and reaction processes.

The chemostat includes remineralization, nitrification, and denitrification reactions using an initial input of detritus (organic nitrogen),  $\text{NO}_3^-$ , and  $\text{O}_2$ , with initial and influent  $\text{NH}_4^+$  and  $\text{N}_2\text{O}$  concentrations set to zero. The output comprises all five state variables including  $\text{NH}_4^+$  and  $\text{N}_2\text{O}$ .  $\text{N}_2$  is not included as an explicit state variable as it is not the primary focus of this research; however, conservation of nitrogen was confirmed by calculating  $\text{N}_2$  produced as the reaction product of  $\text{N}_2\text{O}$  consumption by denitrification. This method allows individual processes that cannot be separated in situ to be studied independently though computer simulation in a controlled environment. Production from nitrification and denitrification less the consumption in denitrification provides the net  $\text{N}_2\text{O}$  production rate that can then be globally integrated to estimate the global net  $\text{N}_2\text{O}$  production rate.

### 2.2.1 Chemostat Initialization

The five state variables used are  $\text{O}_2$ ,  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ ,  $\text{N}_2\text{O}$ , and detritus (organic N).  $\text{O}_2$  and  $\text{NO}_3^-$  influent concentrations are provided by 2018 World Atlas data (Locarnini et al. 2018, Garcia et al. 2018a, 2018b), while  $\text{NH}_4^+$  and  $\text{N}_2\text{O}$  initial concentrations are set to zero. Organic N is calculated from export of particulate carbon from the euphotic zone (100 m), as provided by five Earth System Models: CanESM5, CanESM5-CanOE, CNRM-ESM2-1, GFDL-ESM4, and UKESM1-0-LL (Christian et al. 2022, Séférian et al. 2019, Stock et al. 2020, Yool et al. 2021). The global total sum of carbon exported from the euphotic zone is normalized to  $20 \text{ Pg-C y}^{-1}$  – this is a high estimate, compared to the commonly accepted estimate of  $9 \text{ Pg-C y}^{-1}$  (Resplandy et al. 2019, Nowicki et al. 2022), as only about half of the input of organic matter is remineralized before the system reaches steady state.

Export of particulate carbon is converted to organic N using a Redfield ratio of 106 mol-C:16 mol-N (Redfield 1958) and attenuated with depth using exponential decay at a specified remineralization length scale (see Equation 12 and Figure 13) and converted from flux into an input concentration by dividing by the chemostat dilution rate.

## 3 Results

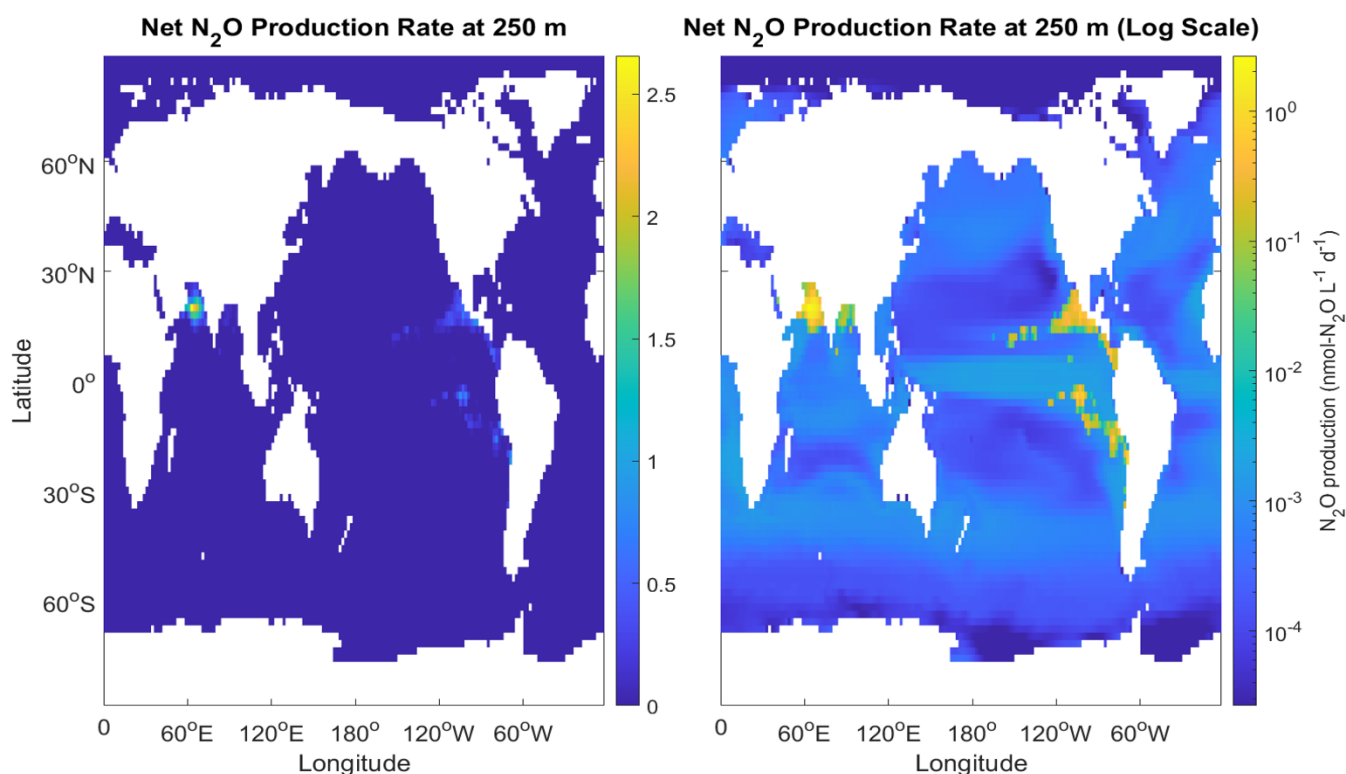

---

The model results are presented in this section, where the chemostat was run until steady state for all locations in a global 3D grid. The output from the chemostat generates reaction rates, which are integrated over each grid box ( $2^\circ$  latitude,  $2^\circ$  longitude, varying depth layer thickness) to estimate global production of  $\text{N}_2\text{O}$  in  $\text{Tg-N y}^{-1}$ . Both net  $\text{N}_2\text{O}$  production rates and  $\text{N}_2\text{O}$  production and consumption rates for individual processes (nitrification production, denitrification production, and denitrification consumption) are generated from this model.

To analyze the sensitivity of ocean  $\text{N}_2\text{O}$  production to input concentrations, environmental conditions, and mathematical parameterizations, changes in the global estimates of  $\text{N}_2\text{O}$  production rates are calculated according to changes in the model input. The base case scenario is presented first in Section 3.1, where global and regional  $\text{N}_2\text{O}$  production rates are established, with the following sections identifying how different data products and varying model parameterizations can affect results.

### 3.1 Global and Regional $\text{N}_2\text{O}$ Production

The global and regional  $\text{N}_2\text{O}$  production rates using the base case scenario for the model are presented here. The base case scenario uses the input conditions described in Section 2, which are then altered individually in the following sections to assess model sensitivity. Instead of attempting to align the base case scenario model output with previous models' estimates of global  $\text{N}_2\text{O}$  production rates, the base case is established according to the most modern and widely accepted parameters, parameterizations, and data products. Since model sensitivity is quantified by comparing global  $\text{N}_2\text{O}$  production rates to the output base case scenario, it is also imperative to provide a clear view of  $\text{N}_2\text{O}$  production rates in both suboxic ( $\text{O}_2 \leq 6 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) and oxic conditions ( $\text{O}_2 > 6 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) to better understand how different production pathways influence the global net total.

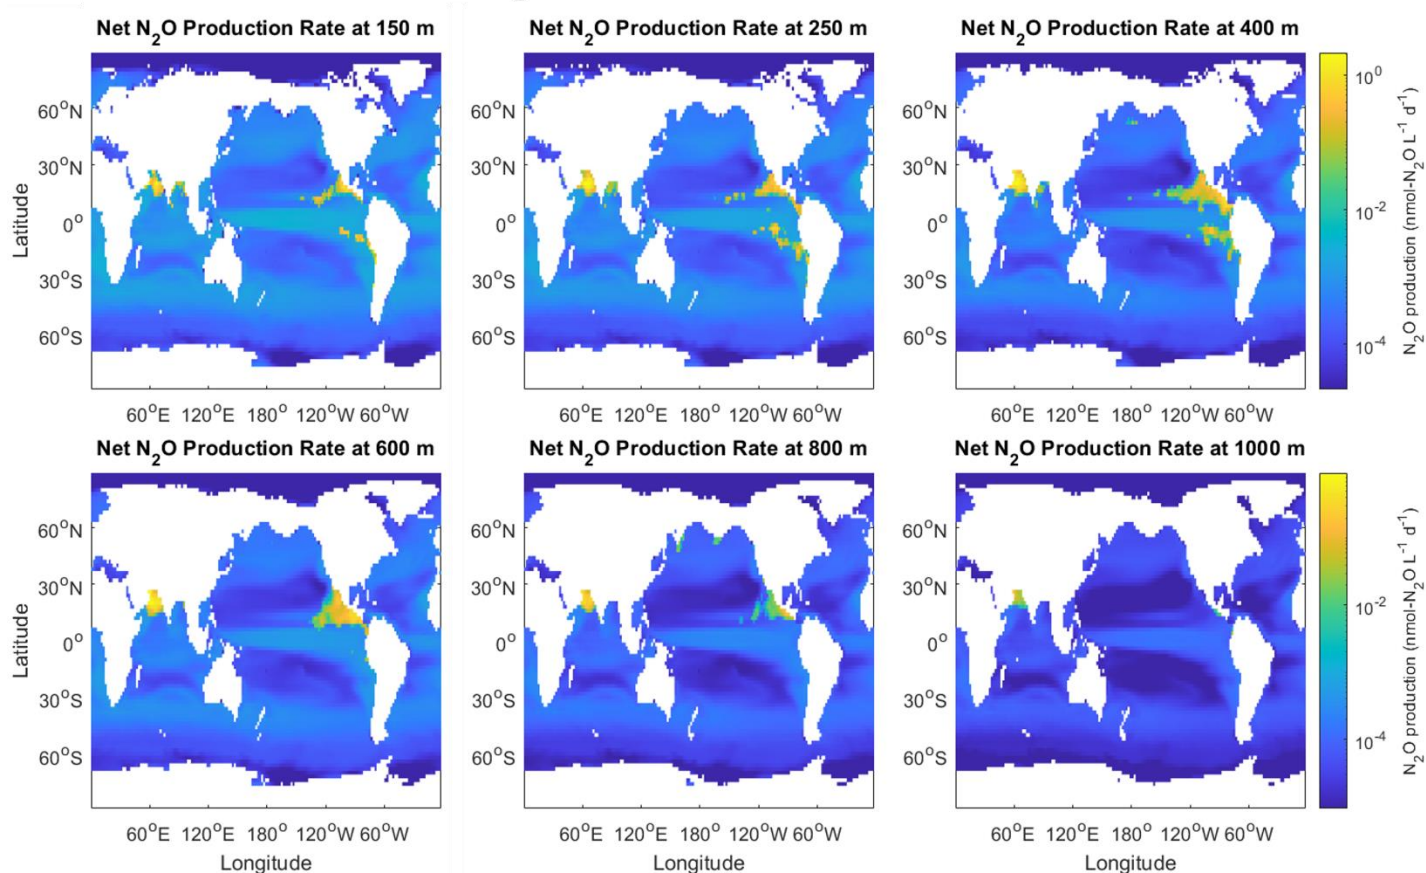

**Figure 15:** Global Net N<sub>2</sub>O Production Rates at 250 m, on a linear (left) and logarithmic (right) colour scale.

Global maps of N<sub>2</sub>O production rates at 250 m are shown in Figure 15, using both linear and logarithmic colour scales, and in Figure 16, where N<sub>2</sub>O production rates are shown for multiple depth layers between 150 and 1000 m using a logarithmic colour scale.

The oxygen deficient zones can be easily identified as hotspots of N<sub>2</sub>O production: N<sub>2</sub>O production rates are visibly higher in ODZs, such as in the Arabian Sea, the sub-tropical Northeast Pacific, and the sub-tropical Southeast Pacific (Figure 15). Figure 15 (left) highlights the strong difference between these regions, while the logarithmic scale (Figure 15, right) also depicts the spatial variability in the oxygenated ocean. These ODZ ‘hotspots of production’ are to be expected, as N<sub>2</sub>O production rates from denitrification tend to be much higher than from nitrification, and because denitrification takes place in suboxic waters.

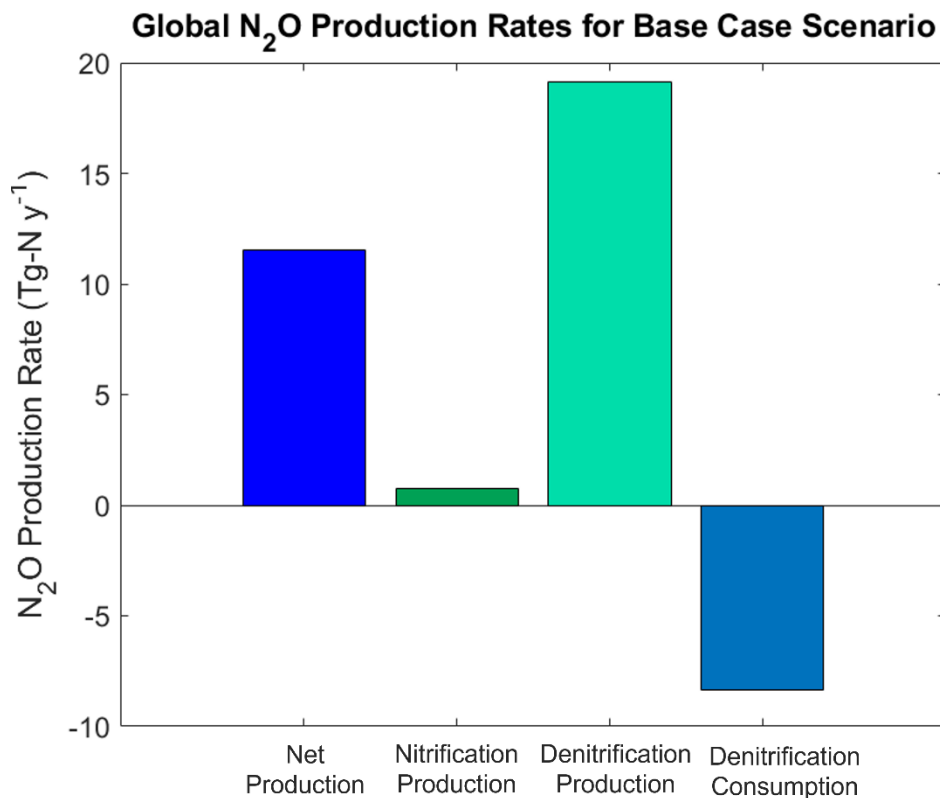

Net N<sub>2</sub>O production in ODZs is large because N<sub>2</sub>O *production* rates by denitrification tend to dominate N<sub>2</sub>O *consumption* rates by denitrification, as N<sub>2</sub>O consumption only occurs in a very narrow range of suboxic O<sub>2</sub> concentrations (approx. 0-2 μmol-O<sub>2</sub> L<sup>-1</sup>) while production occurs in a wider range of O<sub>2</sub> from 0-6 μmol-O<sub>2</sub> L<sup>-1</sup>.

### Global N<sub>2</sub>O Production Rates at Varying Depths

**Figure 16:** Global Net N<sub>2</sub>O Production rates across multiple depth layers from 150 m to 1000 m, using a logarithmic colour scale. Top panels (150-400 m) share a common color scale range, which is different from the color scale range used for the bottom panels (600-1000 m).

The general shape of the ODZ can be observed as the production ‘hotspots’ change in size and intensity (Figure 16) between depth layers. Net N<sub>2</sub>O production rates are higher in the upper depth ranges than in the lower depth ranges, but the ODZs remain visible even at depths up to 800 m. Total N<sub>2</sub>O production rates by nitrification and denitrification and N<sub>2</sub>O consumption rates by denitrification are depicted in Figure 17 and Table 4. Denitrification production is greater than denitrification consumption in ODZs (Figures 15-17) and denitrification production of N<sub>2</sub>O in ODZs is much greater locally than nitrification production in suboxic waters (Figure 20).

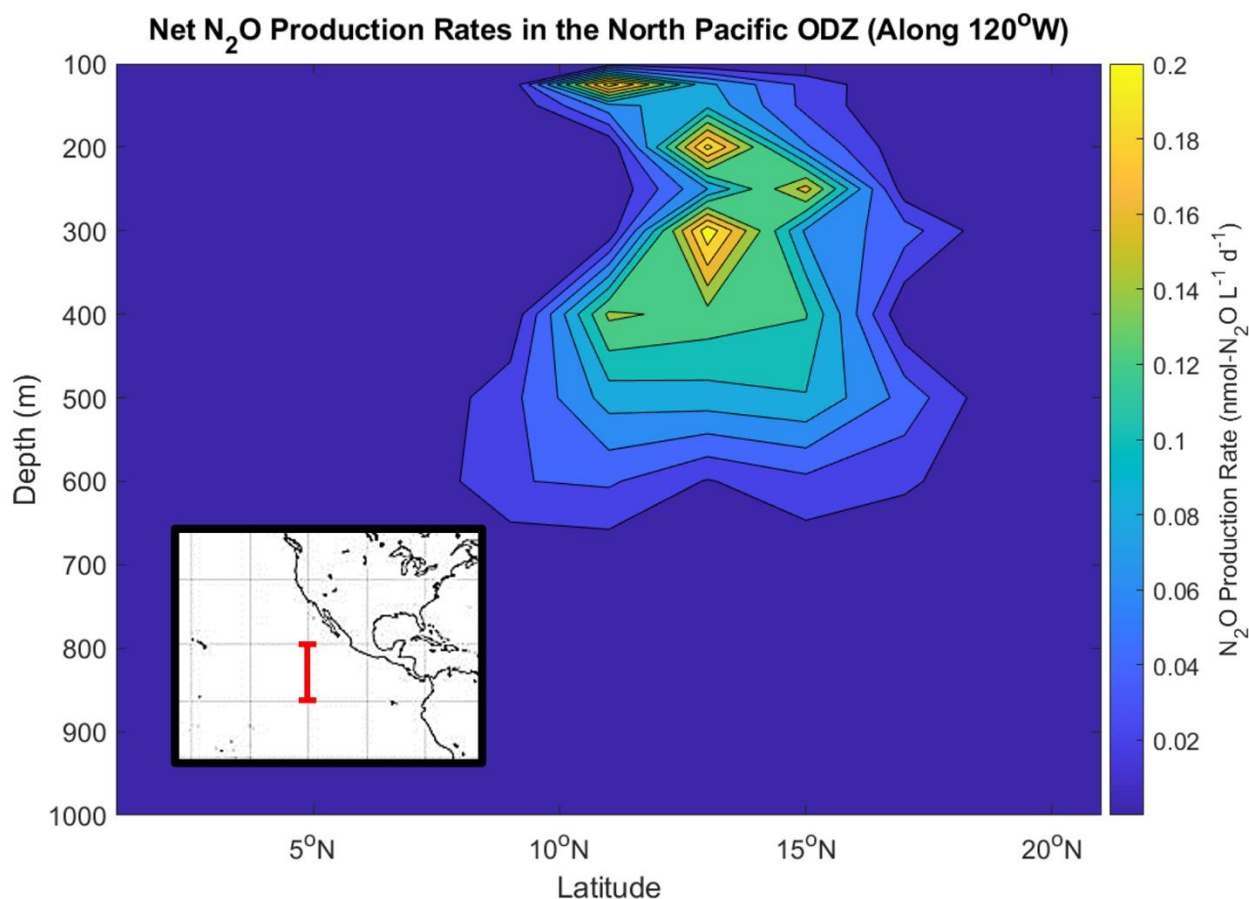

**Figure 17:** Global N<sub>2</sub>O production rates from the base case scenario of the model, including net production, production from nitrification, production from denitrification, and consumption by denitrification. Net production is 11.5 Tg-N y<sup>-1</sup>, with production by denitrification comprising the majority of global net production.

In the base case scenario, denitrification production is the dominant N<sub>2</sub>O production pathway in the global ocean, over 25 times greater than production by nitrification despite denitrification occurring over a much smaller volume of water. Even accounting for denitrification consumption of N<sub>2</sub>O, which removes close to half of the N<sub>2</sub>O produced from denitrification, the net N<sub>2</sub>O production rate from denitrification is over 15 times greater than by nitrification.

**Table 4:** Model global total N<sub>2</sub>O production and consumption rates for base case scenario

Global Net N <sub>2</sub> O Production Rate	11.5 Tg-N y <sup>-1</sup>
Global Nitrification Production Rate	0.740 Tg-N y <sup>-1</sup>
Global Denitrification Production Rate	19.2 Tg-N y <sup>-1</sup>
Global Denitrification Consumption Rate	-8.37 Tg-N y <sup>-1</sup>

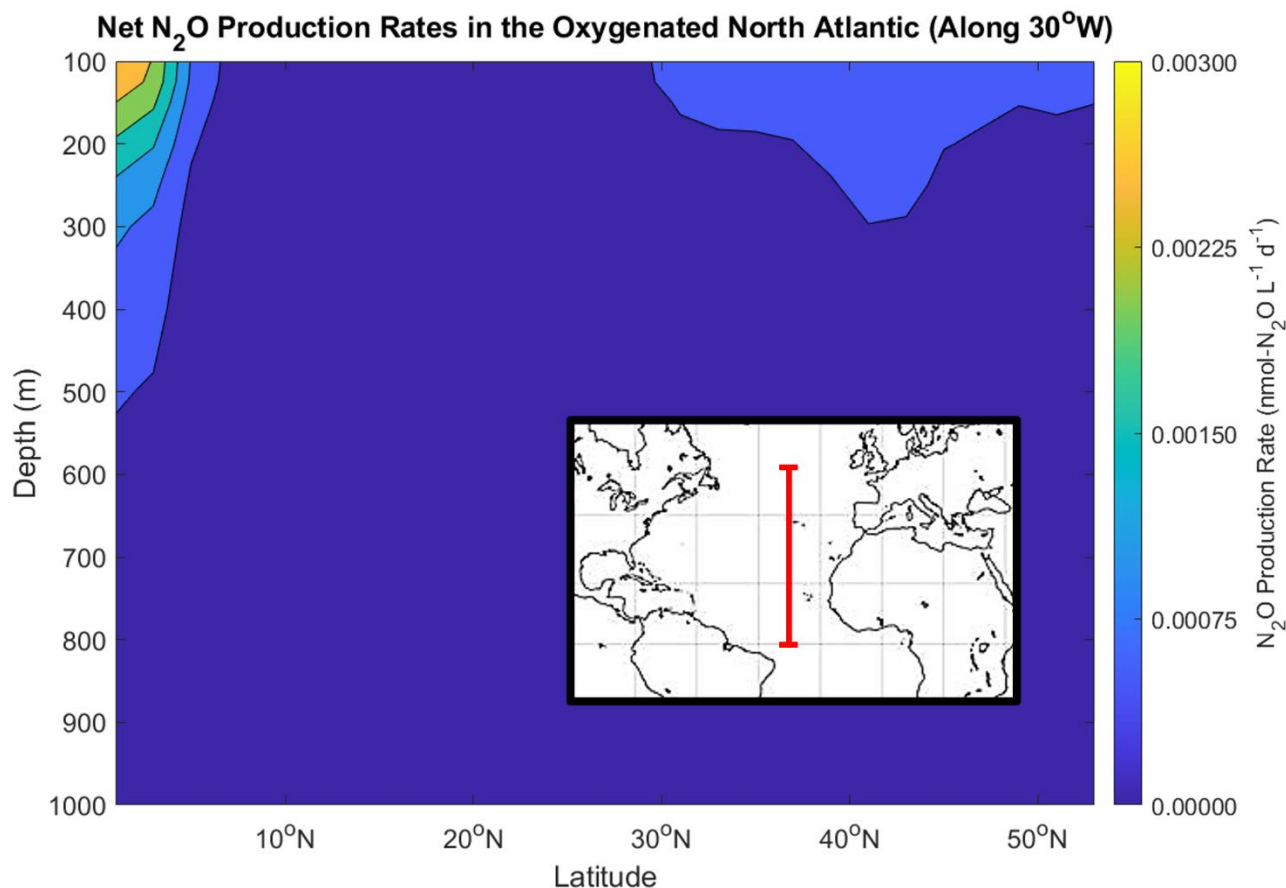

To take a more detailed look at regional differences (particularly between ODZs and the oxic ocean), Figures 18 and 19 depict cross-sections of net  $\text{N}_2\text{O}$  production rates in the North Pacific ODZ along  $120^\circ\text{W}$  (Figure 18) and the oxygenated North Atlantic along  $30^\circ\text{W}$  (Figure 19). The ‘hotspot’ of high  $\text{N}_2\text{O}$  production is easily observed in the North Pacific as it mirrors the shape of the ODZ in this region but does not appear in the oxygenated North Atlantic.

**Figure 18:** Net  $\text{N}_2\text{O}$  production rates in the North Pacific, along  $120^\circ\text{W}$ .

Net  $\text{N}_2\text{O}$  production rates range as high as  $0.2 \text{ nmol-N}_2\text{O L}^{-1} \text{ d}^{-1}$  in the North Pacific when  $\text{O}_2$  reaches the suboxic conditions present in the ODZs but drop rapidly to approx.  $0.02 \text{ nmol-N}_2\text{O L}^{-1}$  when denitrification can no longer occur due to elevated  $\text{O}_2$  concentrations.

While there is regional variation in production of  $\text{N}_2\text{O}$  by nitrification in oxic waters, the range of nitrification  $\text{N}_2\text{O}$  production rates is very small relative to the difference between nitrification and denitrification production rates, and so is not easily seen in the depiction of the North Pacific in Figure 18 (note that Figures 15-16 use logarithmic colour scales, while Figures 18-19 do not). This regional variation is more easily seen in Figure 19, which presents net  $\text{N}_2\text{O}$  production rates in the subtropical North Atlantic – as with most of the oxygenated ocean, only nitrification  $\text{N}_2\text{O}$  production takes place as denitrification requires suboxic  $\text{O}_2$  concentrations, and the highest rates are several orders of magnitude less than in the ODZs.

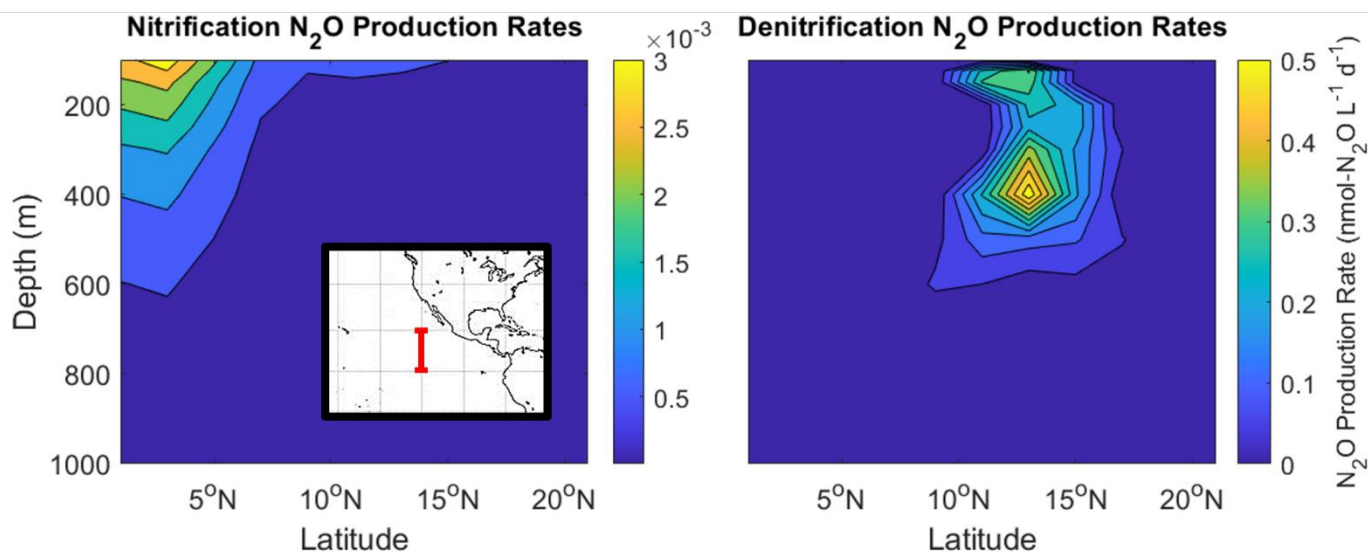

**Figure 19:** Net  $\text{N}_2\text{O}$  production rates in the North Atlantic, along  $30^\circ\text{W}$ . Note that the colour scale range is smaller than in Figure 18, as  $\text{N}_2\text{O}$  production rates in oxic waters are much lower than those in suboxic waters.

The net  $\text{N}_2\text{O}$  production rates in the oxic waters of the North Atlantic do show some variation that is mostly determined by rates of organic matter remineralization, as well as by  $\text{O}_2$  concentrations (Figure 19). Greater availability of detritus and  $\text{O}_2$  near the surface allows higher nitrification rates and so greater nitrification  $\text{N}_2\text{O}$  production rates, even though the higher  $\text{O}_2$  concentrations decreases *yield* of  $\text{N}_2\text{O}$  (see *Equation 5* and Figure 8). As this model allows no physical exchange of water between grid cells, these differences evolve from the  $\text{O}_2$  and detritus data products rather than from movement of water masses.

The highest net  $\text{N}_2\text{O}$  production rates in the North Atlantic reach  $0.003 \text{ nmol-N}_2\text{O L}^{-1} \text{ d}^{-1}$  (Figure 19), while rates at the boundaries of the North Pacific ODZ (where  $\text{O}_2$  is near  $6 \text{ nmol-O}_2 \text{ L}^{-1} \text{ d}^{-1}$ ) range between  $0.02\text{-}0.04 \text{ nmol-N}_2\text{O L}^{-1} \text{ d}^{-1}$ . This indicates that net  $\text{N}_2\text{O}$  production rates are higher not only in the core of the ODZs, but also at the boundaries where both nitrification and denitrification reactions occur.

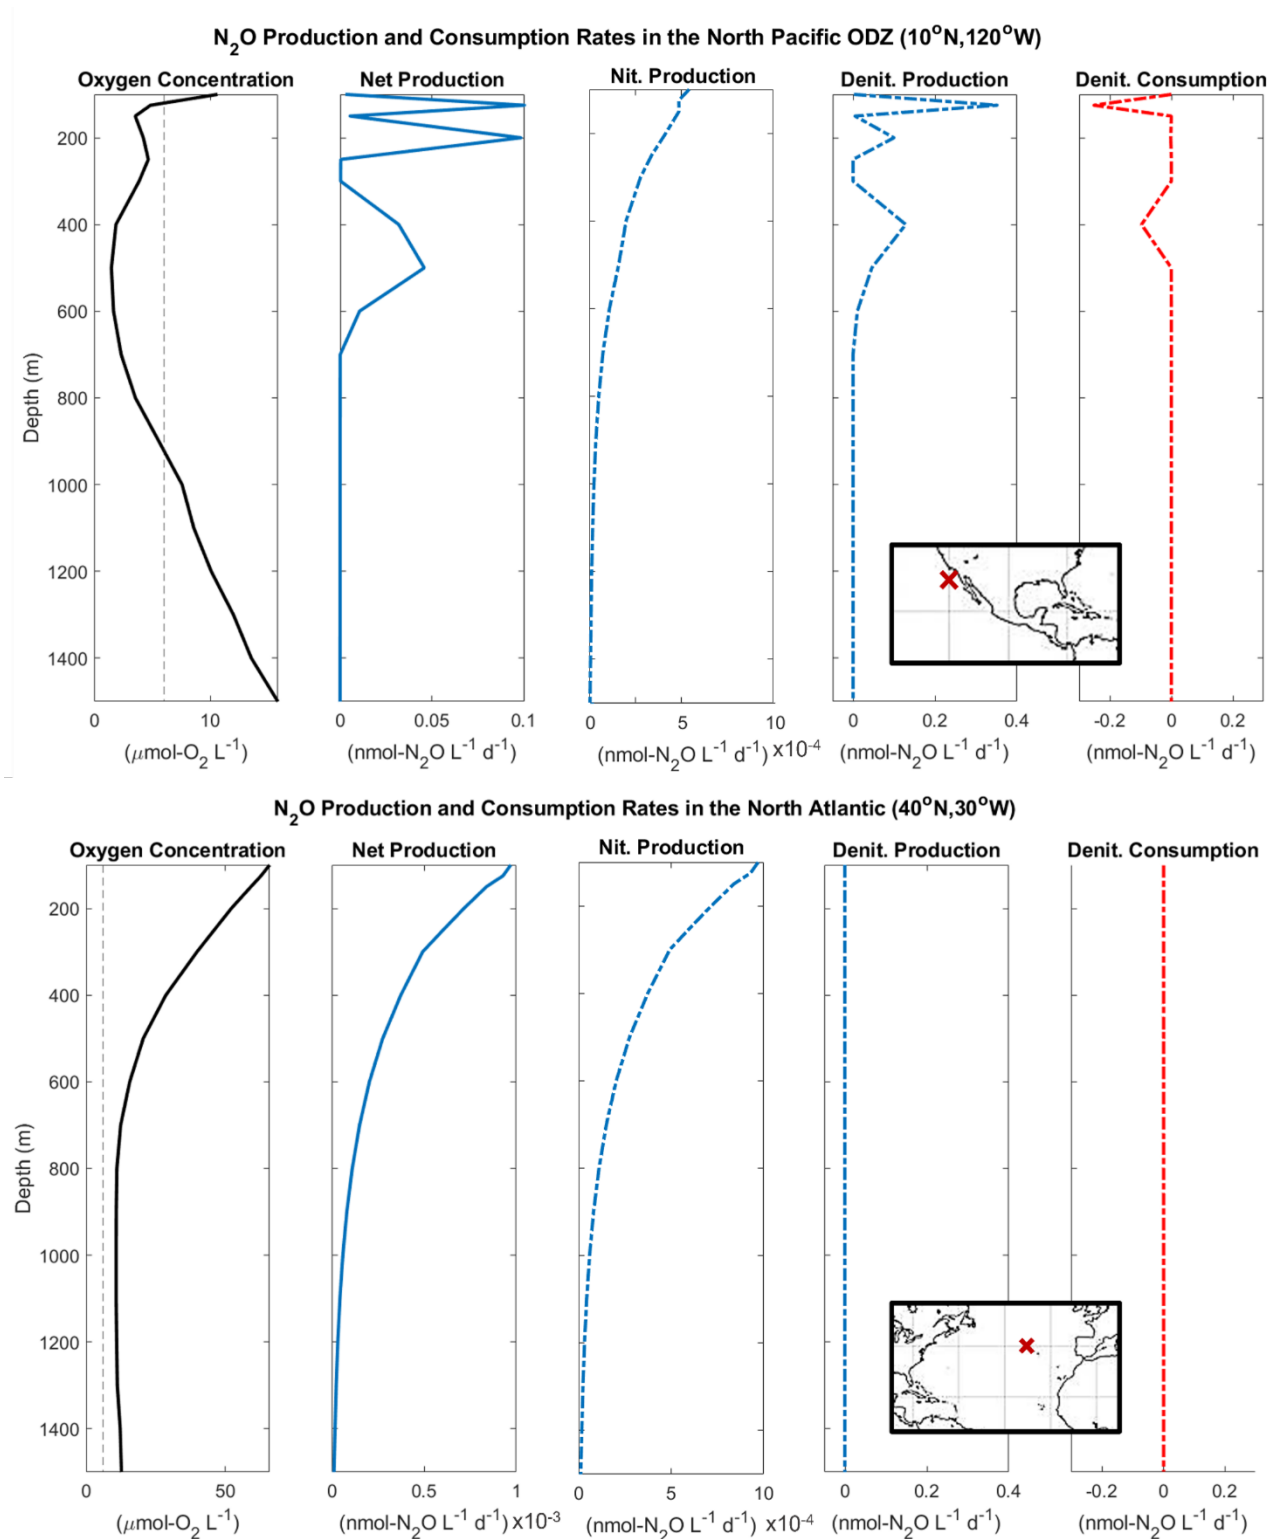

The higher net  $\text{N}_2\text{O}$  production rates at ODZ boundaries could be due to increased yield of  $\text{N}_2\text{O}$  from nitrification at lower  $\text{O}_2$  concentrations, despite the lower overall nitrification rates, or due to denitrification production rates that remain high even within the upper suboxic range ( $5\text{--}6 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) at the ODZ boundaries. To determine which of these reaction mechanisms dominates, a comparison of nitrification and denitrification production rates in the North Pacific ODZ is presented in Figure 20. Note the difference in scale for the colour bars for nitrification versus denitrification – nitrification production rates are three to four orders of magnitude smaller than denitrification production rates.

### $\text{N}_2\text{O}$ Production Rates in the North Pacific ODZ (Along $120^\circ\text{W}$ )

**Figure 20:**  $\text{N}_2\text{O}$  production rates by nitrification (left) and denitrification (right) for a transect along  $120^\circ\text{W}$ .

Nitrification  $\text{N}_2\text{O}$  production rates (Figure 20, left) are more strongly controlled by organic matter supply through remineralization than by  $\text{O}_2$  concentrations, such that the ODZ ‘hotspot’ seen in denitrification  $\text{N}_2\text{O}$  production rates (Figure 20, right) is not present. Nitrification  $\text{N}_2\text{O}$  production rates increase at the surface and towards the equator where there is a greater supply of detritus. Nitrification  $\text{N}_2\text{O}$  production rates are also much lower than denitrification rates for the ODZ region ( $10^\circ\text{N}$  to  $18^\circ\text{N}$ ), emphasizing that denitrification production in ODZs – even at the upper suboxic  $\text{O}_2$  range - has more control over the net  $\text{N}_2\text{O}$  production rates than nitrification production of  $\text{N}_2\text{O}$ .

The regional differences between waters in and at the boundaries of ODZs and in oxic waters far from ODZs can also be illustrated using depth profiles for each of these areas (Figure 21). The rates of N<sub>2</sub>O production by denitrification are much higher than by nitrification in ODZs, and rates of N<sub>2</sub>O consumption by denitrification tend to be substantially smaller than denitrification production rates as N<sub>2</sub>O consumption requires even lower O<sub>2</sub> concentrations than denitrification production. Peaks in the top panel of Figure 21 for denitrification production and consumption occur when O<sub>2</sub> decreases to near-anoxic concentrations, where peaks are larger in shallower waters due to a greater supply of organic matter.

The upper boundaries of the North Pacific ODZ are at approximately 150 m depth, where O<sub>2</sub> concentrations reach below 6 μmol-O<sub>2</sub> L<sup>-1</sup> and denitrification reactions begin (Figure 21, top). Lower boundaries are less defined but appear to reach approx. 1000 m depth. In the North Atlantic O<sub>2</sub> concentrations do not reach below 6 μmol-O<sub>2</sub> L<sup>-1</sup>. Therefore, there is no denitrification and N<sub>2</sub>O production is entirely from nitrification, leading to lower net N<sub>2</sub>O production rates. Nitrification production of N<sub>2</sub>O follows the shape of the attenuation of detrital flux (decreasing exponentially with increasing depth) and has much smaller N<sub>2</sub>O production rates than in the ODZ (Figure 21, bottom).

Despite the fact that ODZs occupy a relatively small volume of water compared to the oxygenated ocean, global net N<sub>2</sub>O production rates by denitrification are higher than global N<sub>2</sub>O production rates by nitrification (Table 3). This reaffirms the conclusion that denitrification is the dominant pathway for N<sub>2</sub>O production – both on a regional scale within ODZs and on a global scale.

## 3.2 Sensitivity to Oxygen

This section details the model's sensitivity to input of O<sub>2</sub>. Effects of spatial and temporal averaging are analyzed alongside variations in the O<sub>2</sub> and detritus data products input to the model. As discussed in the introduction, O<sub>2</sub> is one of the most fundamental controls on N<sub>2</sub>O production rates, especially at the suboxic O<sub>2</sub> concentrations that allow denitrification. This means that data products must be as accurate as possible, especially in the lower O<sub>2</sub> range. Flaws in O<sub>2</sub> data that may generate small differences in other biogeochemical models can have a much more substantial effect on N<sub>2</sub>O production.

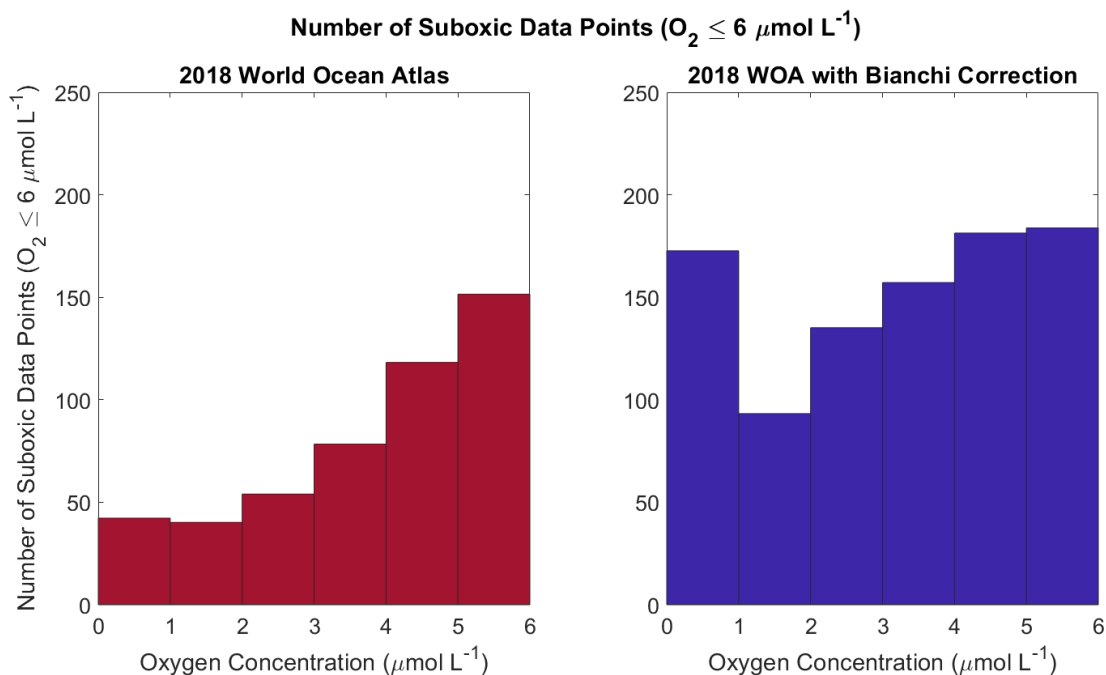

### 3.2.1 Deficiencies in Data Products

The first significant problem in the accuracy of O<sub>2</sub> concentrations arises from the collection of interpolated data from the 2018 World Ocean Atlas (WOA) (Locarnini et al. 2018, Garcia et al. 2018). While WOA provides easily accessible global data products, the interpolation involved tends to 'smear out' low O<sub>2</sub> concentrations in a given region, making suboxic concentrations appear higher than observed in individual profiles. Furthermore, early suboxic O<sub>2</sub> measurements have historically been biased high by an average of 5-6 μmol-O<sub>2</sub> L<sup>-1</sup> yet are still frequently incorporated in modern data sets (Fuenzalida et al. 2009, Ulloa and Pantoja 2009, Naqvi et al. 2010). This was identified and described by Bianchi et al. (2012), who created a simple linear correction method to lower O<sub>2</sub> concentrations to better resemble observations (*Equation 14*). In Equation 14 O<sub>2</sub> is in μmol L<sup>-1</sup> and any concentrations that become negative as a result of this correction are set to zero.

$$[O_{2,\text{corrected}}] = \max \{1.009[O_{2,\text{WOA}}] - 2.523, 0\}$$

(Equation 14)

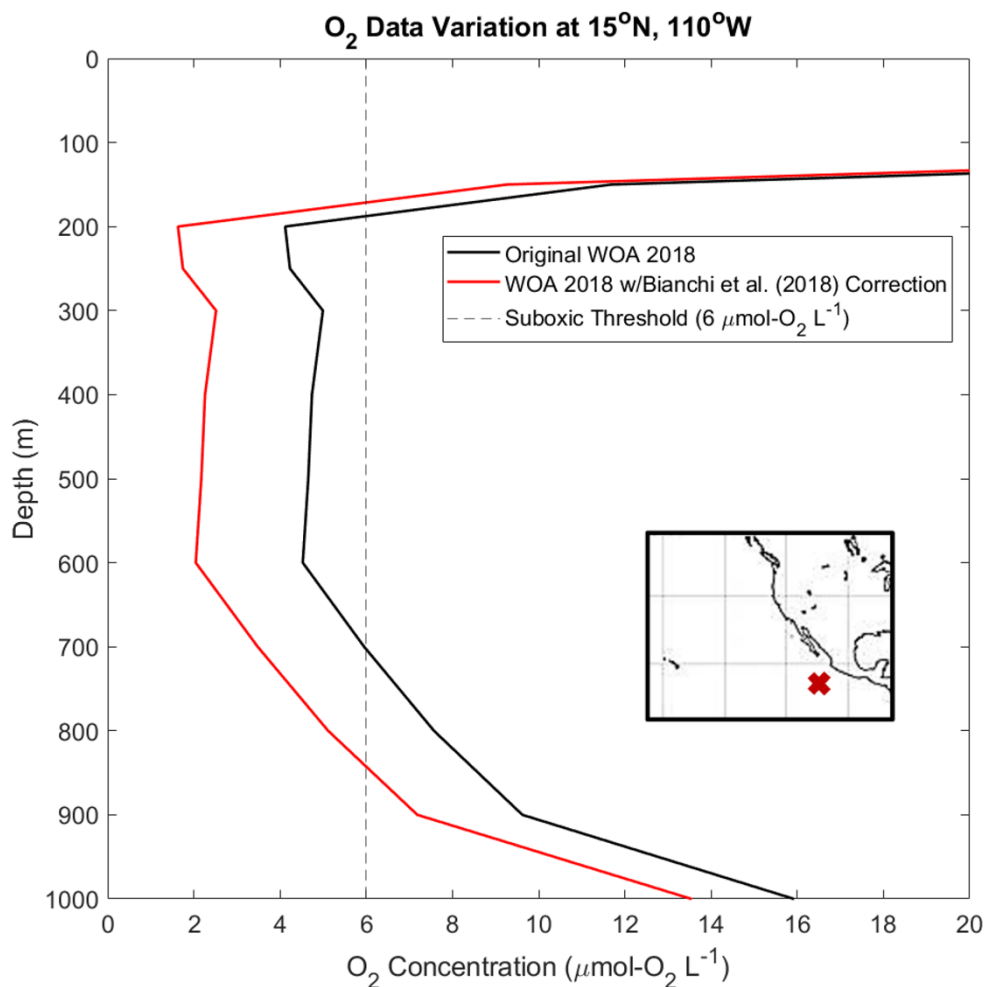

Bianchi et al. (2012) used this method to correct the 2005 WOA data set (Garcia et al. 2006), while this model uses the 2018 WOA data set (Garcia et al. 2018a). The Bianchi correction method provides more data points at low  $O_2$  concentrations in the 2018 WOA data set. The difference is illustrated in Figure 22 using a histogram of the number of suboxic data points ( $O_2 \leq 6 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) using original WOA data and the corrected WOA data.

**Figure 22:** The number of suboxic  $O_2$  data points ( $0-6 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) for the unaltered 2018 World Ocean Atlas  $O_2$  data (left), as well as the corrected  $O_2$  data using a linear correction method from Bianchi et al. (2012) (right), where  $[O_{2,\text{corrected}}] = 1.009 \cdot (O_{2,\text{WOA}}) - 2.523 \text{ } (\mu\text{mol-O}_2 \text{ L}^{-1})$ . If  $[O_{2,\text{corrected}}] < 0$ , concentration is set to zero.

Applying Bianchi's linear  $O_2$  correction method increases the number of data points for each suboxic concentration range ( $0-1 \mu\text{mol-O}_2 \text{ L}^{-1}$ ,  $1-2 \mu\text{mol-O}_2 \text{ L}^{-1}$ , etc.). The total number of suboxic data points increases from 485 to 923 (0.008% to 0.014% of all data points) and provides a larger range of low- $O_2$  data to be input into the model. The correction method also adds a much larger amount of data points in the near-anoxic range ( $0-1 \mu\text{mol-O}_2 \text{ L}^{-1}$ ). This is because all  $O_2$  concentrations that become negative as a result of the correction are set to zero.  $O_2$  concentrations that reach zero (or close to zero) have been measured *in situ* (Revsbech et al. 2009, Ulloa and Pantoja 2009, Bianchi et al. 2012, Thamdrup et al. 2012, Ji et al. 2018), but the volume of water in the  $0-1 \mu\text{mol-O}_2 \text{ L}^{-1}$  range is not known due to lack of data and difficulty of measuring  $O_2$  accurately at extremely low concentrations.

The difference in regional  $O_2$  concentrations can be seen in Figure 23, below, which compares  $O_2$  at a location within the North Pacific ODZ ( $15^\circ\text{N}$ ,  $110^\circ\text{W}$ ) for the original WOA 2018 data and the Bianchi-corrected WOA 2018 data.

**Figure 23:** Depth profiles of O<sub>2</sub> concentration in the North Pacific ODZ (15°N, 110°W), with original WOA 2018 data and WOA 2018 data with Bianchi et al. (2012) correction method.

As the Bianchi correction method is linear, the altered data slightly decreases the O<sub>2</sub> concentrations while maintaining the shape of the curve and overall regional trends in O<sub>2</sub>. Although the Bianchi correction method generates negligible changes to the model in oxic waters, changes within suboxic waters can be substantial – in this location, it provides double the number of suboxic data points than available in the unaltered data set (Figure 22). For this reason, the Bianchi correction method was applied when establishing the base case model scenario.

### 3.2.2 Temporal Averaging

To establish whether seasonal variation in  $O_2$  data affects global  $N_2O$  production rates averaged over one year, the monthly  $O_2$  concentrations were first compared to each other and then to the global average to determine if  $O_2$  varies substantially enough across the seasons to affect global net  $N_2O$  production rates (Figure 24). No substantial difference was found. While  $O_2$  concentrations can vary seasonally in surface waters, this model starts at depths of 100 m.

**Figure 24:** Monthly variation in global  $N_2O$  production rates with monthly  $O_2$  data (Garcia et al. 2018a).

While there are variations in  $N_2O$  production rates according to monthly input of  $O_2$ , there are no discernable trends that follow seasonal cycles (e.g., increased production in March-May for the spring bloom in the Northern Hemisphere and in August-October for the spring bloom in the Southern Hemisphere; seasonal upwelling in April-July from the Eastern Boundary Current (Schwing et al. 1998)). Instead, monthly variation can be attributed to gaps in data collection rather than reflecting true seasonal trends.

However, in the same way that WOA interpolation of data underestimated suboxic  $O_2$  concentrations, leading to high-biased  $O_2$  in ODZs, averaging the  $O_2$  data over the year ‘smoothed out’ many of the low  $O_2$  concentrations that are important for  $N_2O$  production (Figure 25).

**Figure 25:** Histogram of the number of suboxic oxygen data points (0-6  $\mu\text{mol-O}_2 \text{ L}^{-1}$ ) for the 2018 World Ocean Atlas data for annually averaged data (blue) and monthly data (red). Monthly data are normalized to the same number of data points as for the annually averaged data.

The histograms in Figure 25 demonstrate how much O<sub>2</sub> data with concentrations below 6  $\mu\text{mol-O}_2 \text{ L}^{-1}$  is lost when taking an annual average (Figure 25, left) compared to using monthly data (Figure 25, right). Concentrations between 0-4  $\mu\text{mol-O}_2 \text{ L}^{-1}$  are especially affected, where temporal averaging removes 75-100% of the suboxic data points. When the annually averaged O<sub>2</sub> data products are input into the model, they generate very low denitrification production rates even in the cores of the ODZs, and zero denitrification consumption as O<sub>2</sub> does not reach low enough concentrations.

To further illustrate this point, Figure 26 shows global annual N<sub>2</sub>O production rates from the model when using the annually averaged O<sub>2</sub> data or using monthly O<sub>2</sub> data.

**Figure 26:** Global total N<sub>2</sub>O production rates using annually averaged O<sub>2</sub> data (blue) compared to using monthly O<sub>2</sub> data (red).

The net global N<sub>2</sub>O production rates as well as individual reaction rates – especially denitrification production and consumption of N<sub>2</sub>O – are massively affected by temporal averaging of O<sub>2</sub> data products (Figure 26). Net production rates decrease by 65% when using annually averaged O<sub>2</sub> instead of monthly data, as denitrification production rates become greatly reduced by 83%, and denitrification consumption rates reach near zero due to removal of the lowest suboxic data points (<1% of the magnitude of consumption rates when using monthly O<sub>2</sub>). Nitrification N<sub>2</sub>O production rates see negligible effects as annual averaging of data products does not substantially change the O<sub>2</sub> at higher concentrations. Using the annually averaged O<sub>2</sub> (averaged before being input into the model) causes the proportion of nitrification N<sub>2</sub>O production to rise in relation to the denitrification N<sub>2</sub>O production, since denitrification production rates become much smaller and more comparable to nitrification production rates. For this reason, the monthly O<sub>2</sub> climatology data was used for the base case scenario of the model.

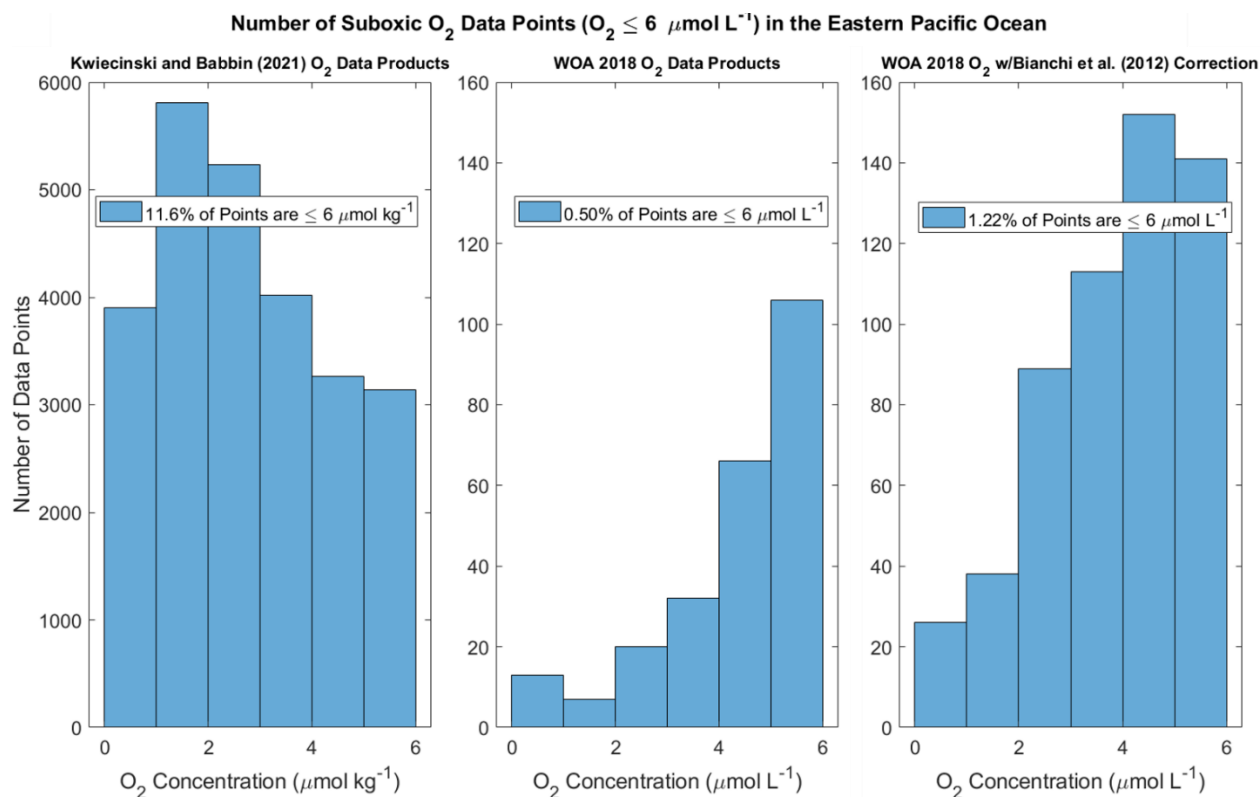

It is important to note that the Bianchi correction method was originally used on annually averaged O<sub>2</sub> data from the 2005 WOA data set, and so applying it to the more recent monthly 2018 WOA data set may produce its own set of uncertainties. Bianchi et al. (2012) were attempting to correct loss of suboxic data points that were in part a result of annual averaging of

WOA data, as compared to instantaneous  $O_2$  concentrations collected *in situ*. Therefore, applying the correction to 2018  $O_2$  data may be an over-correction of monthly data that no longer suffers from annual averaging. Unfortunately, it is difficult to tell if the 2018 WOA data is more accurate with the correction method or without it. It may be that increasing the amount of suboxic data points, even with a redundant correction method, produces a data set that is more accurate to real world conditions. For this reason, and because Kwiecinski and Babbin's (2021) data set does not yet provide an interpolated  $O_2$  data set for the complete global ocean, the Bianchi correction method was maintained and applied to the 2018 WOA data. The assumption here is that, despite improvements from the 2005 to 2018 WOA data sets, the 2018 WOA data still underestimates  $O_2$  concentrations in suboxic waters and so is improved by the increased number of suboxic data points from the Bianchi correction method.

### 3.2.3 Regional Averaging and Newly Available $O_2$ Data Products

Interpolation of observational  $O_2$  data is necessary to creating a global 3D data product, but as detailed in the sections above, it can also cause  $O_2$  concentrations to become biased towards higher concentrations. This is especially true if the observational data are sparse and must be averaged across a large region. Although interpolation techniques have improved, the  $2^\circ \times 2^\circ$  resolution used here necessitates losing some of the more-extreme-suboxic  $O_2$  concentrations so that low  $O_2$  data may be 'smeared out' in a similar fashion to temporal averaging.

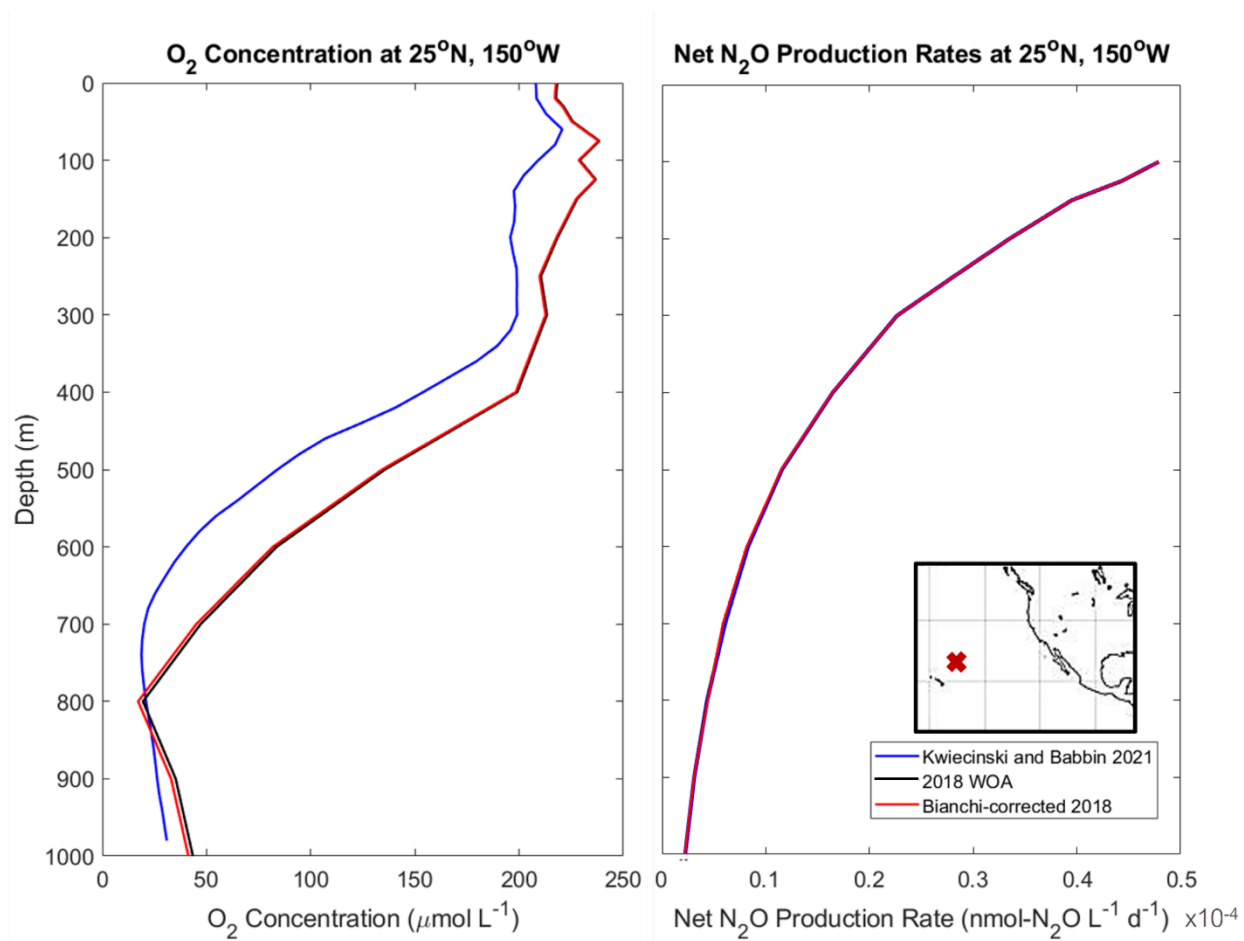

A new method has been proposed that improves understanding of  $O_2$  in suboxic waters – in particular, the size, shape, and intensity of ODZs. Kwiecinski and Babbin (2021) (hereafter referred to as Kwiecinski and Babbin) produced a more precise and accurate representation of the Eastern Tropical Pacific oxygen deficient zone using  $0.5^\circ \times 0.5^\circ$  resolution by finding the vertical gradient of  $O_2$  ( $d[O_2]/dz$ ). In other words, rather than identifying ODZs by  $O_2$  concentrations, Kwiecinski and Babbin defined the cores as regions where  $d[O_2]/dz$  collapse to zero – this allows regions with very low  $O_2$  to be identified without the instrumental issues that affect absolute concentrations. Tens of thousands of data points are analyzed using this method using data provided by both CTD sensors and Argo floats, generating detailed high 3D resolution of the ODZs in the North and South Pacific. The result is a more highly resolved spatial structure of the ODZ than in previously developed data sets, with more  $O_2$  data in the suboxic range. This method has great promise in understanding the shape and intensity of ODZs, but there is still work to be done in order to produce an accurate, high-resolution gridded data set for  $O_2$  concentrations (as opposed to  $d[O_2]/dz$  gradients). The primary benefit of using the Kwiecinski and Babbin data set for  $O_2$  concentrations is a much greater amount of data points, primarily collated from both CTD and Argo float profiles; however, the  $O_2$  concentrations still suffer from the sensor calibration errors inherent to these sampling techniques.

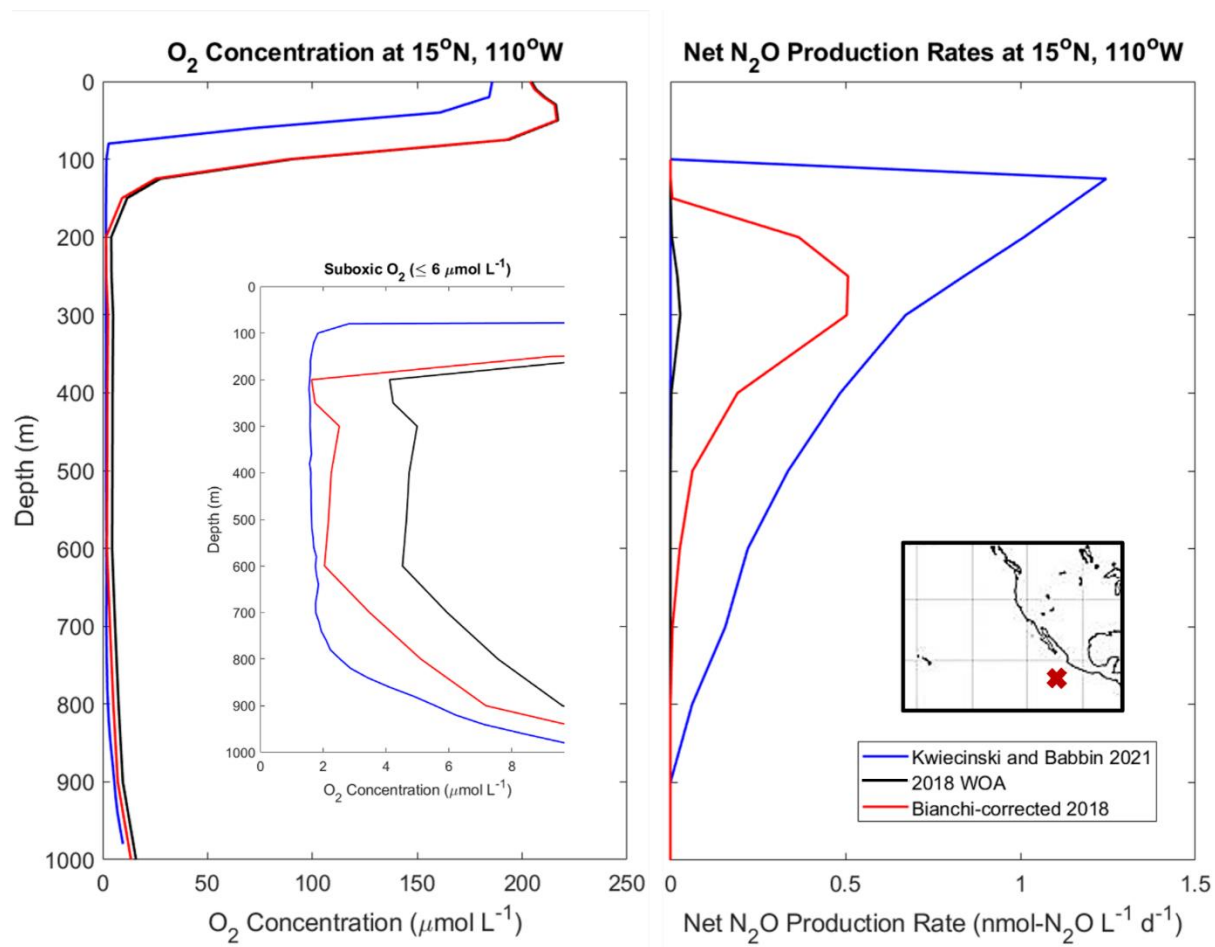

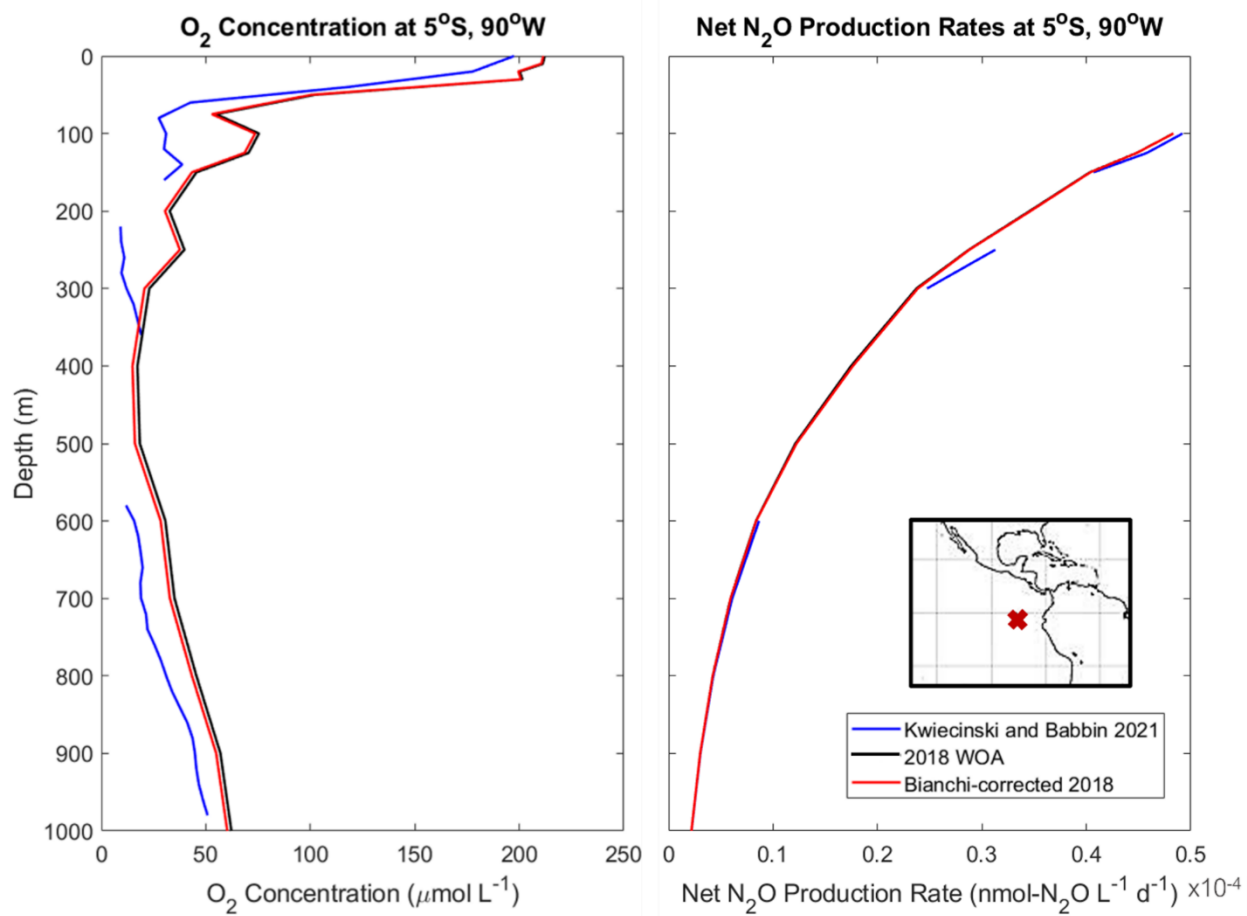

**Figure 27:** Number of suboxic O<sub>2</sub> data points (O<sub>2</sub> ≤ 6 μmol kg<sup>-1</sup>) in the Eastern Pacific Ocean (50°S to 50°N, 180° to 80°W) uses three types of O<sub>2</sub> data products: Kwiecewski and Babbin (2021), WOA2018, and WOA2018 with Bianchi et al. (2012) correction.

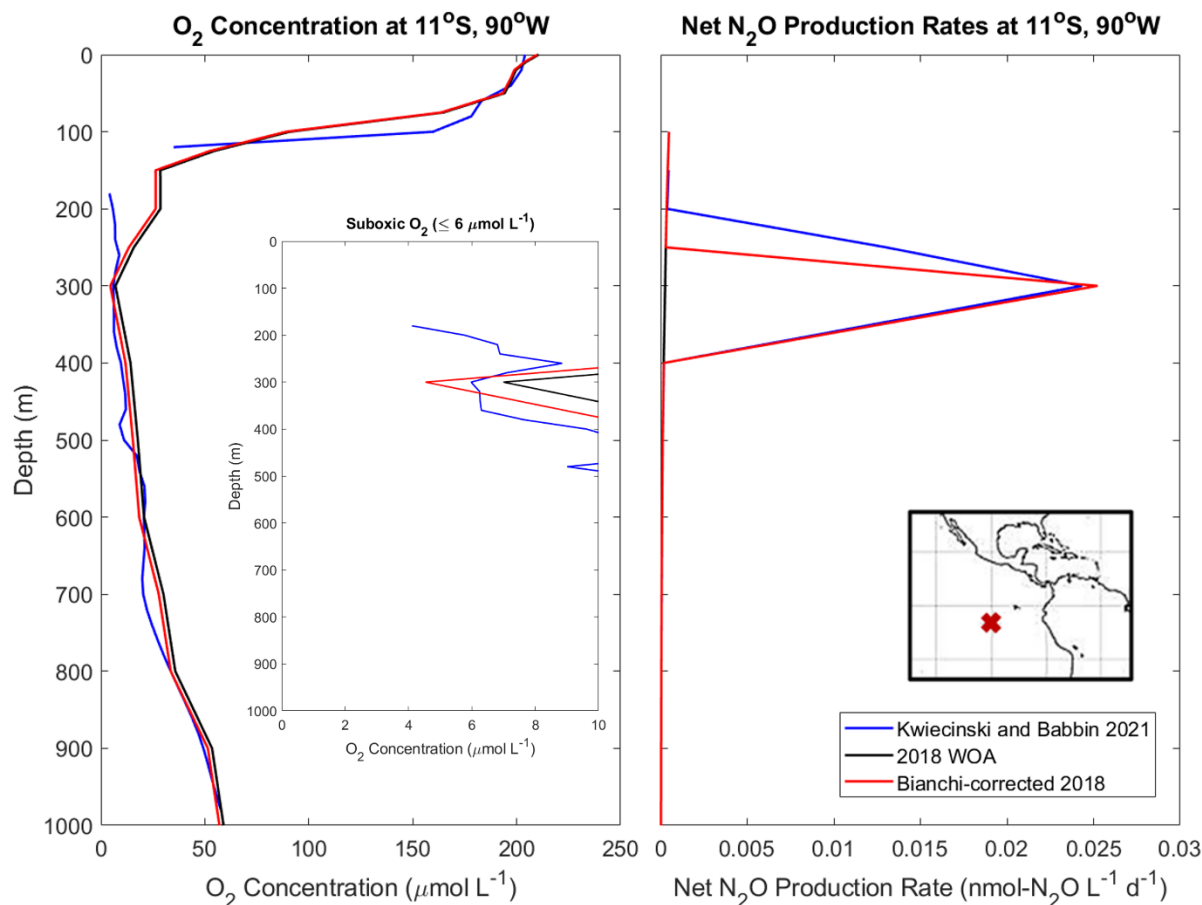

The original 2018 WOA data has 0.50% of total data points as suboxic O<sub>2</sub>, applying the Bianchi correction method increases that to 1.22%, while the Kwiecewski and Babbin data has nearly ten times that at 11.6% of all data points (Figure 27). This comparison between the interpolated WOA data (with and without the Bianchi correction) and the Kwiecewski and Babbin data is not a perfect ‘apples-to-apples’ analogy. Firstly, Kwiecewski and Babbin’s O<sub>2</sub> concentrations are not interpolated to a uniform gridded data set and so do not suffer from the ‘smearing’ of data inherent in the interpolated WOA data. Secondly, the individual profiles considered by Kwiecewski and Babbin for their O<sub>2</sub> analysis were located only in the North and South Pacific ODZ regions and therefore may be biased towards suboxic waters. This is not to say that the suboxic data gathered is inaccurate, but that the amount of data collected in low-O<sub>2</sub> waters may be disproportionate compared to a global data set. It remains difficult to determine whether concentrations at specific locations for any of the three data sets are truly accurate – however, the much greater fraction of suboxic O<sub>2</sub> data points provided by the Kwiecewski and Babbin data products suggests that both the original 2018 WOA and the Bianchi-corrected 2018 WOA data products underestimate the amount of suboxic water in the Pacific ODZs.

A comparison between O<sub>2</sub> and resulting net N<sub>2</sub>O production rates is provided in the Figure 28, which presents depth profiles at multiple locations for all three O<sub>2</sub> data products – Kwiecewski and Babbin (2021), original 2018 WOA data, and Bianchi-corrected WOA data. All of these locations are within the geographic scope of the Kwiecewski and Babbin data set (50°S to 50°N, 180° to 80°W).

**Figure 28:** O<sub>2</sub> Concentrations using three different data sets - Kwiecinski and Babbin 2021 (blue), 2018 WOA (black), and Bianchi-corrected WOA2018 (red) - and net N<sub>2</sub>O production rates using these O<sub>2</sub> data products. When the difference between WOA2018 and Bianchi-corrected WOA2018 is negligible, the black WOA2018 line may not be visible.

Examples of how the new Kwiecinski and Babbin O<sub>2</sub> data products may affect net N<sub>2</sub>O production rates in different regions are depicted above in Figure 28. The first two locations are in the North Pacific although only the location at 15°N, 110°W is located in the North Pacific ODZ. The second two locations are in the South Pacific, and while both are located in the South Pacific ODZ, only the location at 11°S, 90°W reaches suboxic concentrations low enough for denitrification to occur. When O<sub>2</sub> is lower than 6 μmol-O<sub>2</sub> L<sup>-1</sup>, denitrification production of N<sub>2</sub>O increases net N<sub>2</sub>O production rates over 3-4 times in magnitude (note the x-axis range for net N<sub>2</sub>O production rate) to display peaks of N<sub>2</sub>O production. The other two locations have lower N<sub>2</sub>O production rates due to nitrification being the only N<sub>2</sub>O production process and have rates several orders of magnitude less than the denitrification production rates.

The difference in O<sub>2</sub> depth profiles between the WOA data (and Bianchi-corrected WOA data) and the Kwiecinski and Babbin data is immediately apparent. While the Bianchi correction slightly decreases O<sub>2</sub> from the original WOA while maintaining the same shapes of the curves, the Kwiecinski and Babbin data products generate substantially lower O<sub>2</sub> concentrations for all locations. The shapes of the curves are generally maintained, though to a lesser degree than the

difference between Bianchi-corrected and original WOA data, but the depth of the oxic-anoxic interface is substantially shallower – especially in ODZ locations.

The WOA and Bianchi-corrected WOA data shows an oxycline that is anywhere from 25-100 m deeper than in Kwiecinski and Babbin's data for the North Pacific, though it is only slightly deeper (<25 m) for the South Pacific. The emergence of the oxic-anoxic interface and ODZs at shallower depths can have a substantial effect on the net N<sub>2</sub>O production rates. At shallow depths closer to the euphotic zone there is a greater input of organic matter and substrates to be used in N<sub>2</sub>O production reactions – combining this with low O<sub>2</sub> at shallow depths will permit N<sub>2</sub>O production by denitrification to occur at greater rates than would be possible at deeper locations.

In addition to a generally shallower oxic-anoxic interface, the gradient in the oxycline is much sharper in the Kwiecinski and Babbin data set than in the WOA data sets, reaching low O<sub>2</sub> concentrations more quickly and providing a larger region of suboxic O<sub>2</sub> waters capable of supporting denitrification and high N<sub>2</sub>O production rates. Increased volumes of suboxic waters combined with a greater supply of detrital organic matter at shallower depths therefore can result in higher net production by denitrification, where denitrification production rates that are already much higher than rates of production from nitrification are further increased.

This can be seen in the North Pacific ODZ (15°N, 110°W; Figure 28b) where net N<sub>2</sub>O production rates are greatly increased when using the Kwiecinski and Babbin data set compared to either of the WOA data sets. The N<sub>2</sub>O profile mirrors the shape of O<sub>2</sub> concentrations where the ODZ is visible at a shallower depth and at lower concentrations for Kwiecinski and Babbin data compared to WOA and Bianchi-corrected WOA data. The suboxic O<sub>2</sub> concentrations for the Kwiecinski data set are sustained over a greater range of depths than for WOA, which causes sustained high denitrification N<sub>2</sub>O production. This leads to an increase in maximum net N<sub>2</sub>O production rates at this location when using Kwiecinski and Babbin's data (1.25 nmol-N<sub>2</sub>O L<sup>-1</sup> d<sup>-1</sup>) rather than the original WOA data (0.028 nmol-N<sub>2</sub>O L<sup>-1</sup> d<sup>-1</sup>) – nearly 45 times different in magnitude. Interestingly, this is not true for all locations with suboxic O<sub>2</sub>, as the location in the South Pacific (11°S, 90°W) has fairly similar O<sub>2</sub> concentrations across all data sets.

If the Kwiecinski and Babbin data set were applied to regional or global estimates of N<sub>2</sub>O production rates, its likely that similarly higher rates would occur across ODZ regions. However, for the time being these water column N<sub>2</sub>O production and consumption rates are available only for depth profiles at specific locations.

The effect of higher N<sub>2</sub>O production rates due to denitrification processes is restricted to ODZs and suboxic waters that permit denitrification – while the O<sub>2</sub> in oxygenated waters sees similar trends between the Kwiecinski and Babbin data sets and the WOA data sets, the effect on N<sub>2</sub>O production rates is negligible. For all regions where O<sub>2</sub> remains > 6 μmol-O<sub>2</sub> L<sup>-1</sup>, nitrification is the only N<sub>2</sub>O production process, and nitrification is less affected by O<sub>2</sub> than denitrification. Even the large differences in O<sub>2</sub> between the Kwiecinski and Babbin data and the WOA data sets produce negligible differences in N<sub>2</sub>O production rates.

It should also be noted that while the vertical gradient of O<sub>2</sub> ( $d[O_2]/dz$ ) and its related term  $fODZ$  used by Kwiecinski and Babbin have been interpolated to create a 3D data set, the actual O<sub>2</sub> concentrations have not been similarly reconciled. Interpolation of the O<sub>2</sub> concentrations and reconciliation with the resolution of other existing data products was determined to be outside the scope of this study and so the Bianchi-corrected WOA data products were maintained for the base case scenario of the model. However, future N<sub>2</sub>O models will benefit from the Kwiecinski

and Babbin (2021) data, and so this section provides a brief analysis of the impact of using this O<sub>2</sub> scheme compared to original 2018 WOA and Bianchi-corrected 2018 WOA.

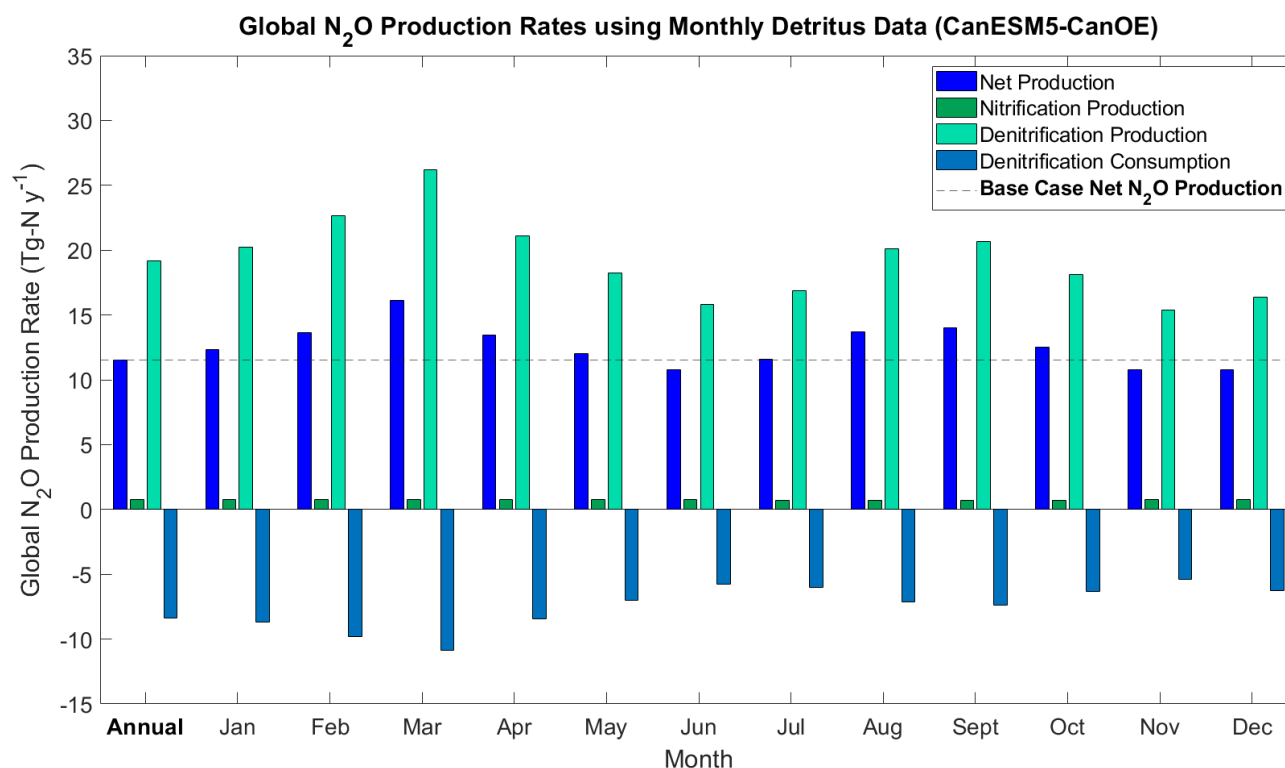

### 3.3 Sensitivity to Organic Matter Remineralization

Detritus (D) is the substrate for remineralization: oxic remineralization of organic matter provides the NH<sub>4</sub><sup>+</sup> used in nitrification that is subsequently converted into both N<sub>2</sub>O and NO<sub>3</sub><sup>-</sup>, while suboxic remineralization uses organic matter as a substrate alongside NO<sub>3</sub><sup>-</sup> for the first step of denitrification (reduction of NO<sub>3</sub><sup>-</sup> to N<sub>2</sub>O). While NO<sub>3</sub><sup>-</sup> data products are provided by WOA to be used as the model initial conditions, the influent concentration of NH<sub>4</sub><sup>+</sup> is set to zero and so NH<sub>4</sub><sup>+</sup> availability is entirely controlled by the supply of detritus.

The data products used to provide influent detritus concentrations are the export of particulate carbon (EPC) from the euphotic zone as generated by five Earth System Models – CanESM5, CanESM5-CanOE, CNRM-ESM2-1, GFDL-ESM4, and UKESM1-0-LL (see Sections 2.1 and 2.2). The base case scenario of the model uses CanESM5-CanOE. To determine how differences in EPC among models affects N<sub>2</sub>O production and consumption rates, spatial and temporal variation are analyzed, as well as differences in the parameterization of detrital flux attenuation with depth (Equation 12).

#### 3.3.1 Temporal Variation

Organic matter can vary seasonally as well as spatially, and unlike O<sub>2</sub> the effects of seasonal changes remain recognizable at well depths below 100 m (Figure 29). To determine how temporal variation affects global N<sub>2</sub>O production rates, monthly EPC data was used to generate global N<sub>2</sub>O production rates, which can then be compared to global N<sub>2</sub>O production rates using annually averaged EPC from the base case scenario (Figure 30).

**Figure 29:** Global N<sub>2</sub>O production rates using monthly or annually averaged export production (CanESM5-CanOE). The base case scenario (annually averaged export) is in bold.

The temporal variation in detritus does match seasonal trends of a large spring bloom in February-April from the Northern Hemisphere, followed by a smaller bloom in August-October from the spring bloom in the Southern Hemisphere (Figure 29). However, the difference between using monthly data and annually averaged data is relatively small in terms of global net N<sub>2</sub>O production rates. Using the annually averaged EPC only varies slightly from using the monthly data, with a relatively small change in global net N<sub>2</sub>O production rates (Figure 30).

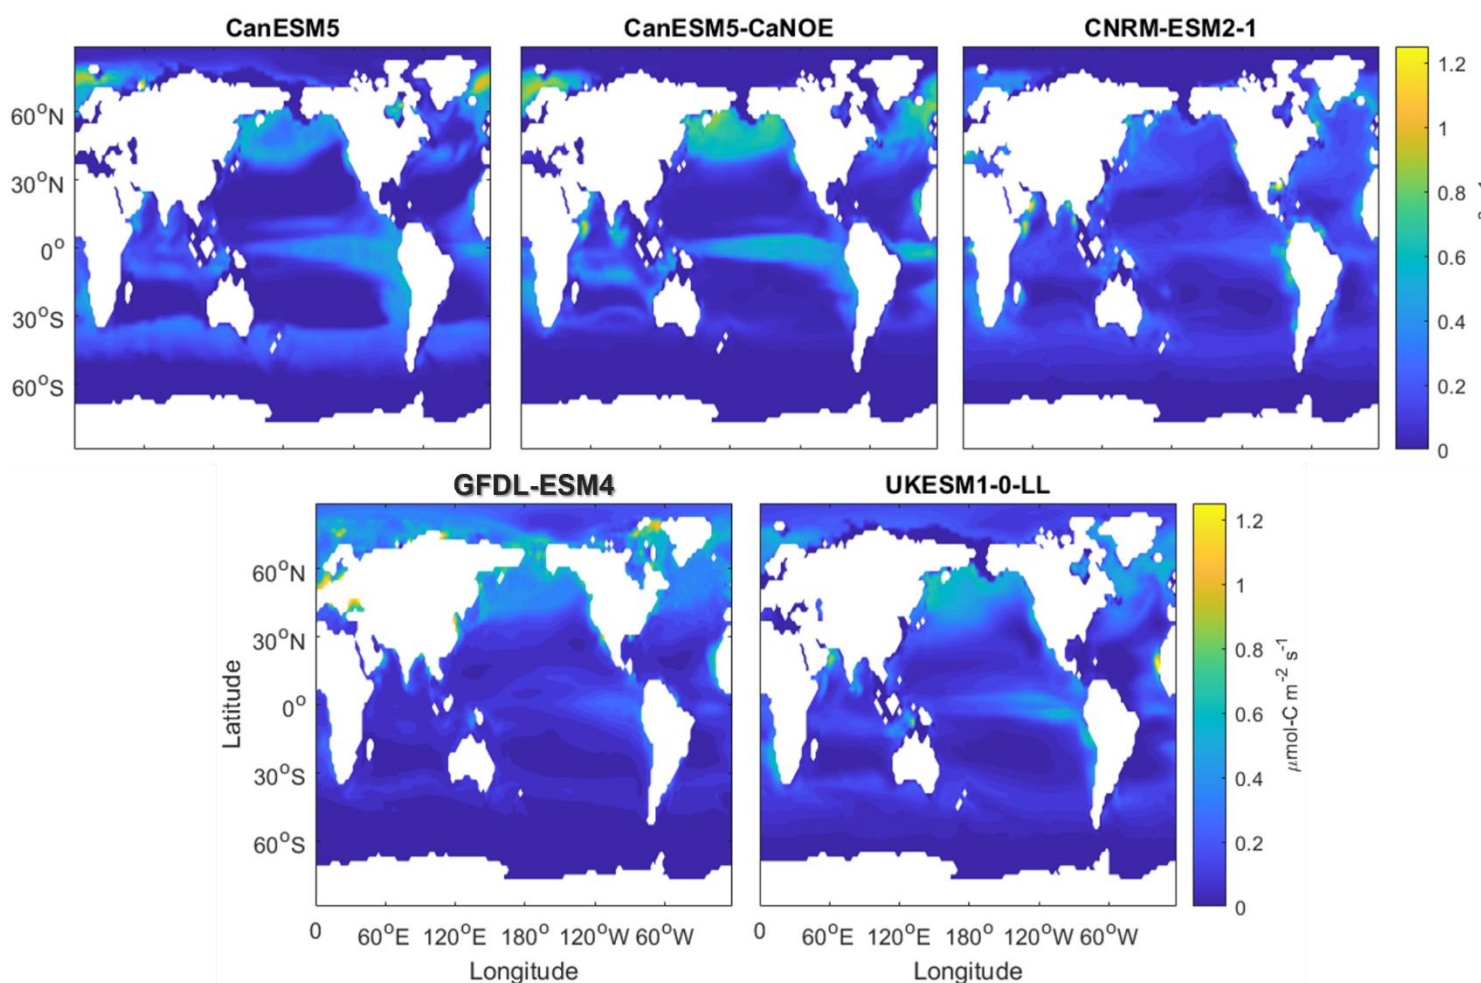

**Figure 30:** Global N<sub>2</sub>O production rates using monthly or annually averaged export production (CanESM5-CaNOE).

There is a slight change in denitrification production rates accompanied by a larger change in denitrification consumption rates, but the effect on net N<sub>2</sub>O production rates remains small at only an 8.9% difference. This implies that the model is not strongly sensitive to the seasonality of detritus flux.

### 3.3.2 Spatial Variation

To determine the effects of spatial variation among the EPC data from the five models, the global total of exported carbon from each is first normalized to 20 Pg-C y<sup>-1</sup> (as in the base case scenario). This allows only regional variation between models to be assessed without discrepancies in the total amount of export affecting the results (Figure 31).

### Comparison of Export Production of Carbon from Different GCMs at 100 m

**Figure 31:** Export production of carbon from the euphotic zone as generated by five Earth System Models: CanESM5, CanESM5-CanOE, CNRM-ESM2-1, GFDL-ESM4, and UKESM1-0-LL.

Figure 31 provides a visualization of the spatial variation of particulate carbon flux from the euphotic zone. Figure 32 shows how this affects the  $\text{N}_2\text{O}$  production rates from the model. The interactions among detritus,  $\text{O}_2$ ,  $\text{NO}_3^-$ , temperature, and solar irradiance all combine to influence  $\text{N}_2\text{O}$  production and consumption rates, but keeping the global total EPC constant allows for estimation of the sensitivity to spatial distribution of EPC among models.

The choice of EPC data products substantially affects global  $\text{N}_2\text{O}$  production even when the data products use the same global total EPC (Figure 32). Denitrification production and consumption in particular are the most affected.

**Figure 32:** Global  $N_2O$  production and consumption rates using export production of particulate organic matter from the euphotic zone from different Earth System Models. Bottom panel depicts the nitrification production rates in the top panel at a larger scale. Base case (CanESM5-CaNOE) is in bold.

When there is higher EPC overlying the ODZs, there tends to be higher net  $\text{N}_2\text{O}$  production rates due to greater substrate supply for use in denitrification reactions. If there is more organic matter available in the regions overlying ODZs, then there will be more reactants to fuel denitrification in suboxic waters. Differences between the spatial distribution of EPC from choice of Earth System Model have a moderate effect on net  $\text{N}_2\text{O}$  production rates of up to 43.7%.

### 3.3.3 Detrital Flux Attenuation with Depth

Detritus attenuates with depth exponentially according to *Equation 12*, where organic matter flux from the euphotic zone decreases with depth according to a constant remineralization length scale ( $\alpha_{RLS}$ ). For the base case scenario, detrital flux is calculated using CanESM5-CanOE model output and attenuated with an inverse remineralization length scale,  $\alpha_{RLS} = 0.003 \text{ m}^{-1}$ . To determine how strongly the remineralization parameterization affects global net  $\text{N}_2\text{O}$  production rates,  $\alpha_{RLS}$  is varied between 0.001 and 0.02  $\text{m}^{-1}$  to see how flux attenuation with depth affects the input of detritus to the model, and so the remineralization rate and  $\text{N}_2\text{O}$  production (Figure 33).

**Figure 33:** Effect of changing the remineralization length scale on the attenuation of detritus flux with depth (top) and the rate of detritus input into each model layer (bottom). Base case scenario ( $\alpha_{RLS} = 0.003 \text{ m}^{-1}$ ) is in bold.

The value of  $\alpha_{RLS}$  affects the shape of the curve of flux attenuation with depth (Figure 33, top), where a low  $\alpha_{RLS}$  creates very slow attenuation with depth of the detritus input into the model and a higher  $\alpha_{RLS}$  implies a rapid detritus concentration decay with depth (Figure 33, bottom). The

bottom panel depicts the detritus input into the model as derived from integration across depth layers using the attenuation of detritus flux from the top panel.

**Figure 34:** Effect of changing the inverse remineralization length scale ( $\alpha_{RLS}$ ) on global N<sub>2</sub>O production rates (using export production from CanESM5-CanOE).

The global N<sub>2</sub>O net production rate decreases with increasing remineralization length scale ( $\alpha_{RLS}$ ), except at the lowest value of  $0.001 \text{ m}^{-1}$  (Figure 34). The decrease in net N<sub>2</sub>O production rates from  $\alpha_{RLS} = 0.003 - 0.020 \text{ m}^{-1}$  is likely because there is decreasing availability of detritus in the regions where O<sub>2</sub> is low enough for denitrification production and consumption of N<sub>2</sub>O. Higher  $\alpha_{RLS}$  provides a greater amount of organic matter at shallower depths and attenuates much more quickly in the 300-600 m region where ODZs occur (Figure 33). The total integrated remineralization of organic matter for the water column may not be small itself, but the depth at which organic matter supply is high will affect N<sub>2</sub>O production. When  $\alpha_{RLS} = 0.001 \text{ m}^{-1}$ , much of the detritus is transported to greater depths that are well oxygenated and so unlikely to undergo denitrification to produce (and consume) N<sub>2</sub>O.

While there are lower net N<sub>2</sub>O production rates, this is due to the strong influence from the denitrification reactions. Denitrification production and consumption rates increase and decrease alongside each other, since high denitrification production of N<sub>2</sub>O provides higher N<sub>2</sub>O concentrations to be consumed by the completion of the denitrification reaction. In contrast to the generally lower denitrification rates with higher  $\alpha_{RLS}$ , nitrification N<sub>2</sub>O production rates increase with higher  $\alpha_{RLS}$ . This is due to the proportion of organic matter that reaches the seafloor without undergoing remineralization and consequent nitrification, rather than interactions between O<sub>2</sub> and nitrification yield of N<sub>2</sub>O. Higher  $\alpha_{RLS}$  leads to greater total detritus concentrations input into the model – over three times in magnitude for the range of  $\alpha_{RLS}$  tested. Overall, this can lead to net N<sub>2</sub>O production rates changing up to 35% when varying  $\alpha_{RLS}$ .

### 3.4 Sensitivity to Temperature and Solar Irradiance

Remineralization (both oxic and suboxic) is affected by temperature, and nitrification is affected by solar irradiance. In this section, these properties will be investigated to determine how strongly they affect  $\text{N}_2\text{O}$  production rates.

#### 3.4.1 Seasonal Variations in Temperature

Spatial variations in temperature are accounted for by applying World Ocean Atlas temperature data to remineralization rates using the Arrhenius equation (see Section 2.1); however, temperature does not vary strongly at depths below 100 m. Nevertheless, seasonal variations may affect remineralization processes – namely, remineralization of detritus to  $\text{NH}_4^+$  and suboxic remineralization of organic matter reducing  $\text{NO}_3^-$  to  $\text{N}_2\text{O}$  (denitrification). Figure 35 depicts global net  $\text{N}_2\text{O}$  production rates using annually averaged and monthly temperature data.

**Figure 35:** Global net  $\text{N}_2\text{O}$  production rates using annually averaged and monthly temperature data. Base case scenario (annually averaged temperature data) is in bold. Note the small range on the y-axis scale.

While there is temporal variation in global net N<sub>2</sub>O production rates over the course of the year, the effect is not substantial as rates range from approximately 11.5 to 11.6 Tg-N<sub>2</sub>O y<sup>-1</sup>, resulting in a maximum total difference of 1.1%. The difference between using an annual average of temperature data and using the average of simulations using monthly data is only a 0.21% difference. For this reason and to decrease processing time, the base case scenario of using annually averaged temperature data products was maintained.

### 3.4.2 Seasonal Variations in Solar Irradiance

As with the temperature experiment above, sensitivity to seasonal solar irradiance is also evaluated here. Since solar irradiance inhibits nitrification, nitrification N<sub>2</sub>O production rates are the primary quantity affected. As with seasonal trends in temperature, temporal changes in solar irradiance produce very little effect on global nitrification N<sub>2</sub>O production rates (Figure 36), where the difference between the maximum rates (June) and the minimum rates (January) amounted to 0.20% of the total. The effect on global *net* N<sub>2</sub>O production rates is even smaller, with a maximum difference of 0.014%.

**Figure 36:** Global N<sub>2</sub>O production rates by nitrification using location-specific, monthly data for solar irradiance (PAR) from ISCCP (Bishop et al. 1997). Base case scenario (annually averaged irradiance) is in bold. Note the small range on the y-axis scale.

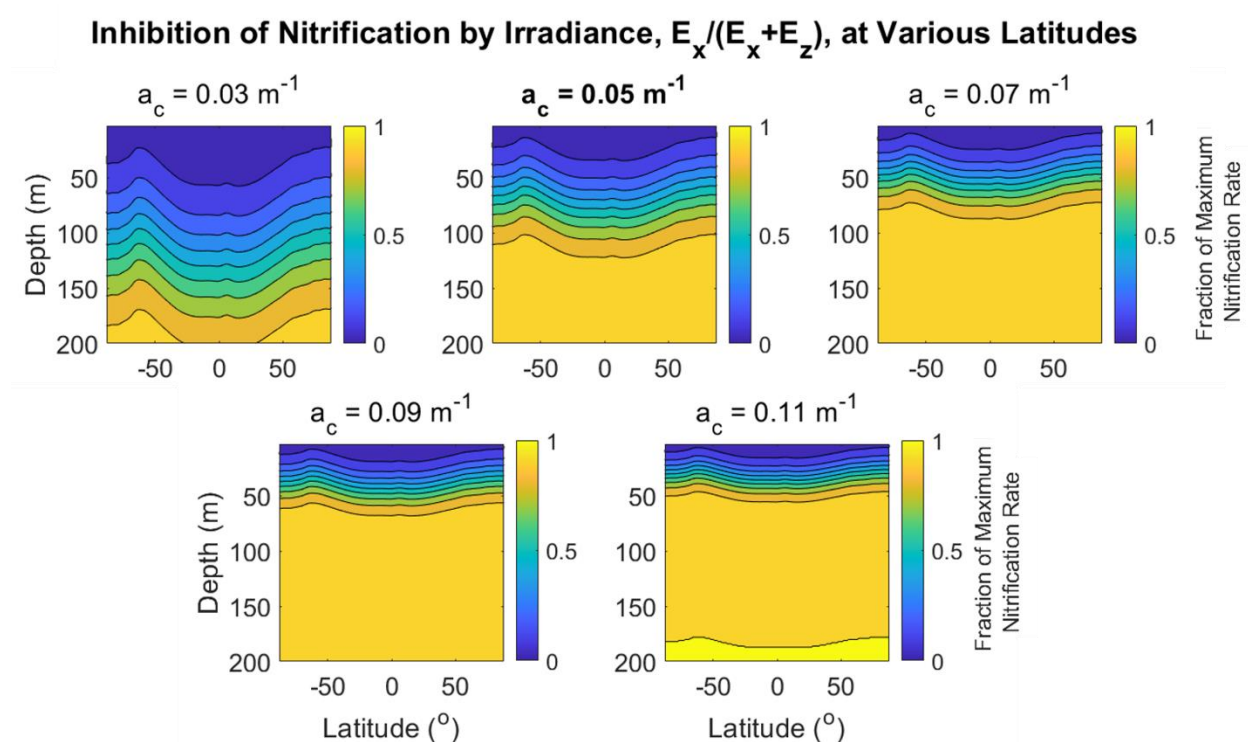

A quantitative comparison between using all months of solar irradiance data products and taking an annual average of the output nitrification N<sub>2</sub>O production rates, versus using a pre-generated annual average also resulted in negligible differences - less than a 0.1% change in global nitrification N<sub>2</sub>O production rates and a near-zero change in global net N<sub>2</sub>O production rates (Figure 36).

The small influence of temporal changes in solar irradiance on N<sub>2</sub>O production rates is to be expected. The penetration of solar irradiance past depths of approximately 100 m is limited and

so only influences a small region of the global model, and nitrification production of  $N_2O$  is minor compared to denitrification.

### 3.4.3 Solar Irradiance Light Penetration Depth

While there is very little change in global net  $N_2O$  production rates when using monthly solar irradiance data products, it is possible that a greater effect could be seen if the light penetration depth was altered. This model uses a constant light attenuation coefficient ( $a_c$ ) that does not fully represent how water clarity in different regions would influence how much solar irradiance penetrates the ocean's depths. To determine the effect on global net and nitrification  $N_2O$  production rates,  $a_c$  was varied from its base case ( $0.05 \text{ m}^{-1}$ ) across a range of values: 0.01, 0.05, 0.10, 0.25, and  $0.50 \text{ m}^{-1}$ . These  $a_c$  coefficients were then applied to the irradiance inhibition factor  $E_x/(E_x+E_z)$  (see Equations 11-12) and observed with depth across varying latitudes (Figure 37, 38).

**Figure 37:** Inhibition of nitrification by irradiance at various latitudes using a range of light attenuation coefficients,  $a_c$ . Calculated using zonally and annually averaged surface solar irradiance. Base case scenario ( $a_c=0.05 \text{ m}^{-1}$ ) is in bold.

Increasing  $a_c$  effectively decreases the depth of the region affected by solar irradiance – with  $a_c$  greater than the base case of  $0.05 \text{ m}^{-1}$  irradiance has almost no effect on nitrification in the model as  $E_x/(E_x+E_z)$  remains close to 1 at depths greater than 100 m (Figure 37). Decreasing  $a_c$  to  $0.03 \text{ m}^{-1}$  increases the inhibition of nitrification by solar irradiance as the light permeation depth increases to approximately 200 m (Figure 37). To gain another perspective on how  $a_c$  controls the nitrification inhibition factor over depth, a series of depth profiles was created using a constant PAR of  $50 \text{ mol m}^{-2} \text{ d}^{-1}$  (Figure 38).

**Figure 38:** Effect of varying the light attenuation coefficient ( $a_c$ ) on the irradiance inhibition factor,  $E_x/(E_x+E_z)$ , using a common surface PAR =  $50 \text{ mol m}^{-2} \text{ d}^{-1}$ . Base case scenario ( $a_c=0.05 \text{ m}^{-1}$ ) is in bold.

Increasing the light attenuation coefficient,  $a_c$ , decreases the depth at which solar irradiance, and so the irradiance inhibition factor,  $E_x/(E_x+E_z)$ , will affect nitrification within the model. A very low  $a_c$  of  $0.01 \text{ m}^{-1}$  would cause inhibition of nitrification due to solar irradiance to occur at depths up to 1000 m, while a large  $a_c$  of  $0.50 \text{ m}^{-1}$  means that nitrification will not be inhibited by irradiance past approximately 10 m (Figure 38). Since this model does not account for depths above 100 m, this would mean that there would be no effect by solar irradiance on nitrification or nitrification  $\text{N}_2\text{O}$  production rates.

To see how varying the light penetration effect may change global nitrification  $\text{N}_2\text{O}$  production rates, the model was run using the range of  $a_c$  light attenuation coefficients (Figure 39). Global net  $\text{N}_2\text{O}$  production rates and denitrification  $\text{N}_2\text{O}$  production and consumption rates show negligible change and so are not depicted.

**Figure 39:** Global nitrification N<sub>2</sub>O production rates using varying light attenuation coefficients ( $a_c$ ). Base case scenario ( $a_c=0.05\ m^{-1}$ ) is in bold.

The effect of changing the light attenuation coefficient on global nitrification N<sub>2</sub>O production rates is quite small, as is expected given that the model only involves reactions below the euphotic zone (100 m). Even an  $a_c$  of  $0.03\ m^{-1}$  will only result in a relatively small effect on global nitrification N<sub>2</sub>O production.

However, global models include nitrification within the euphotic zone may see a stronger effect on global N<sub>2</sub>O production rates with varying  $a_c$ . For the purposes of this model, which only considers N<sub>2</sub>O-relevant reactions below the euphotic zone, the base case coefficient of  $0.05\ m^{-1}$  was maintained and sensitivity to this parameter is considered to be weak.

### 3.5 Parameter Sensitivity Analysis

The following parameterizations use specific parameters that are either poorly quantified in literature, have a wide range of possible values, or have no literature basis at all. The sensitivity of the model will generate a better idea of which parameters have the most control over global N<sub>2</sub>O production rates, as well as the values that best produce results in line with past literature estimates.

#### 3.5.1 Half-Saturation Constants for Nitrification and Suboxic Remineralization ( $fO_{2,AmOx}$ and $fNO_{3,rem}$ )

Two key parameterizations control nitrification and remineralization processes through availability of the electron acceptors required for the reaction to proceed.  $fO_{2,AmOx}$  determines the nitrification rate as a function of availability of O<sub>2</sub>, while  $fNO_{3,rem}$  ensures that suboxic remineralization/denitrification rates are limited by the availability of NO<sub>3</sub><sup>-</sup>. As the half-

saturation constants for each of these equations are not well established in literature, the model's sensitivity to these qualities is evaluated here to determine how strongly these constants affect global  $N_2O$  production rates.

### $f_{O_2,AmOx}$

The nitrification reaction rate is directly affected by availability of  $O_2$  and  $NH_4^+$  (Equation 5), and indirectly affected by how detritus concentrations and temperature affect remineralization of detritus to  $NH_4^+$ . The effects of changing the half-saturation constant ( $K_{O_2,AmOx}$ ) on  $f_{O_2,AmOx}$  are shown in Figure 40. For this experiment, the tested  $K_{O_2,AmOx}$  values were 0.1, 1, 3, 5, 10, and 30  $\mu\text{mol-O}_2 \text{ L}^{-1}$ .

**Figure 40:** Relative rate of ammonium oxidation vs.  $O_2$  using varying half-saturation constants ( $K_{O_2,AmOx}$ ). Base case scenario ( $K_{O_2,AmOx}=5 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) is in bold.

A higher  $K_{O_2,AmOx}$  generates a more gradual decrease in  $f_{O_2,AmOx}$  as  $O_2$  decreases, while a lower  $K_{O_2,AmOx}$  produces a sharper curve such that  $O_2$  has little control on nitrification except at very low  $O_2$  concentrations. It is worth noting that nitrification rates are affected by  $O_2$  through  $f_{O_2,AmOx}$ , but nitrification  $N_2O$  production rates are also affected by  $O_2$  as  $O_2$  concentrations affect the yield of  $N_2O$  from nitrification, which is discussed below.

It is important to maintain nitrification in the lower  $O_2$  range, as there is evidence of nitrification occurring at low  $O_2$  (Bristow et al. 2016, Ji et al. 2018). If  $K_{O_2,AmOx}$  is too large, nitrification will be strongly inhibited under low  $O_2$ . For this reason, the base case scenario uses a  $K_{O_2,AmOx}$  value of 5  $\mu\text{mol-O}_2 \text{ L}^{-1}$  to help represent the variability of nitrification rates in the oxygenated ocean as

well as near the boundaries of ODZs – however, this remains an uncertain quantity and will be discussed more in the following Discussion section (Section 4.1).

To determine how this assumption of  $K_{O_2,AmOx} = 5 \mu\text{mol-O}_2 \text{ L}^{-1}$  lies in relation to other half-saturation constants in terms of global  $\text{N}_2\text{O}$  production, the range of  $K_{O_2,AmOx}$  values were applied to the model to observe the resultant range of global  $\text{N}_2\text{O}$  production rates by nitrification (Figure 41).

**Figure 41:** Global  $\text{N}_2\text{O}$  production rates from nitrification with varying  $f_{O_2,AmOx}$  half-saturation constant ( $K_{O_2,AmOx}$ ). Base case scenario ( $K_{O_2,AmOx} = 5 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) is in bold.

While changing the half-saturation constant  $K_{O_2,AmOx}$ , does have an effect on global nitrification production rates (Figure 41) – namely, that increased  $K_{O_2,AmOx}$  results in lower nitrification  $\text{N}_2\text{O}$  production – the effect is negligible in terms of global net  $\text{N}_2\text{O}$  production rates. Global net  $\text{N}_2\text{O}$  production rates with varying  $K_{O_2,AmOx}$  only vary between approximately 11.4-11.6  $\text{Tg-N}_2\text{O y}^{-1}$  for a maximum 1.0% difference.

$f_{NO_3,rem}$

$f_{NO_3,rem}$  uses a half-saturation constant ( $K_{NO_3,rem}$ ) and a Michaelis Menten-styled parameterization similar to  $f_{O_2,AmOx}$ , but refers to decreasing suboxic remineralization rates with decreasing availability of  $NO_3^-$ . Both suboxic and oxic remineralization pathways consume organic matter (detritus), but the oxic pathway uses  $O_2$  as an electron acceptor while the suboxic pathway uses  $NO_3^-$  as an electron acceptor. Suboxic remineralization approaches 100% of total remineralization at low  $O_2$ , so  $f_{NO_3,rem}$  is used to ensure that suboxic remineralization rates decrease to zero as  $NO_3^-$  approaches zero.

**Figure 42:** Relative rate of denitrification vs.  $NO_3^-$  with varying half-saturation constant ( $K_{NO_3,rem}$ ). Base case scenario ( $K_{NO_3,rem} = 5 \mu\text{mol-NO}_3^- \text{ L}^{-1}$ ) is in bold.

Unfortunately, there are very few literature estimates of the dependence on  $\text{NO}_3^-$  in terms of a half-saturation constant, and so  $K_{\text{NO}_3, \text{remin}}$  was set to be equal to  $5 \mu\text{mol-NO}_3^- \text{L}^{-1}$ . To determine how strongly this half-saturation constant may affect global  $\text{N}_2\text{O}$  production rates and global net  $\text{N}_2\text{O}$  production rates, a range of  $K_{\text{NO}_3, \text{remin}}$  values were tested: 0.1, 1, 3, 5, 10, and  $30 \mu\text{mol-NO}_3^- \text{L}^{-1}$ . These half-saturation constants were then plotted against various  $\text{NO}_3^-$  concentrations to see how the reaction rate decays with limited  $\text{NO}_3^-$  availability (Figure 42).

The base case  $K_{\text{NO}_3, \text{remin}}$  half-saturation constant was chosen to be  $5 \mu\text{mol-NO}_3^- \text{L}^{-1}$  as it shows a more gradual reaction rate decay in the ‘medium’ range of  $\text{NO}_3^-$ . When  $\text{NO}_3^-$  concentrations are between  $20\text{-}50 \mu\text{mol-NO}_3^- \text{L}^{-1}$  there is approximately a 20% decrease in reaction rates, while lower  $\text{NO}_3^-$  concentrations see a much greater rate decay. Higher half-saturation constants show very strong decreases in rates even in the ‘medium’ range of  $\text{NO}_3^-$ , and along with the requirement of suboxic remineralization occurring in the  $0\text{-}6 \mu\text{mol-O}_2 \text{L}^{-1}$  this was deemed too strong. The lower values of the half-saturation constant show little change in the reaction rate in the ‘medium’ range of  $\text{NO}_3^-$ .

**Figure 43:** Global  $\text{N}_2\text{O}$  production rates with varying  $f\text{NO}_{3, \text{remin}}$  half-saturation constant ( $K_{\text{NO}_3, \text{remin}}$ ). Base case scenario ( $K_{\text{NO}_3, \text{remin}} = 5 \mu\text{mol-NO}_3^- \text{L}^{-1}$ ) is in bold.

To see how strongly this choice affects global  $\text{N}_2\text{O}$  production, the model was run using each  $K_{\text{NO}_3, \text{remin}}$  and comparing the output global  $\text{N}_2\text{O}$  production (and consumption) rates alongside each other (Figure 43). The impact of varying  $K_{\text{NO}_3, \text{remin}}$  on net  $\text{N}_2\text{O}$  production rates is moderate, amounting to up to a maximum 41.7% difference.

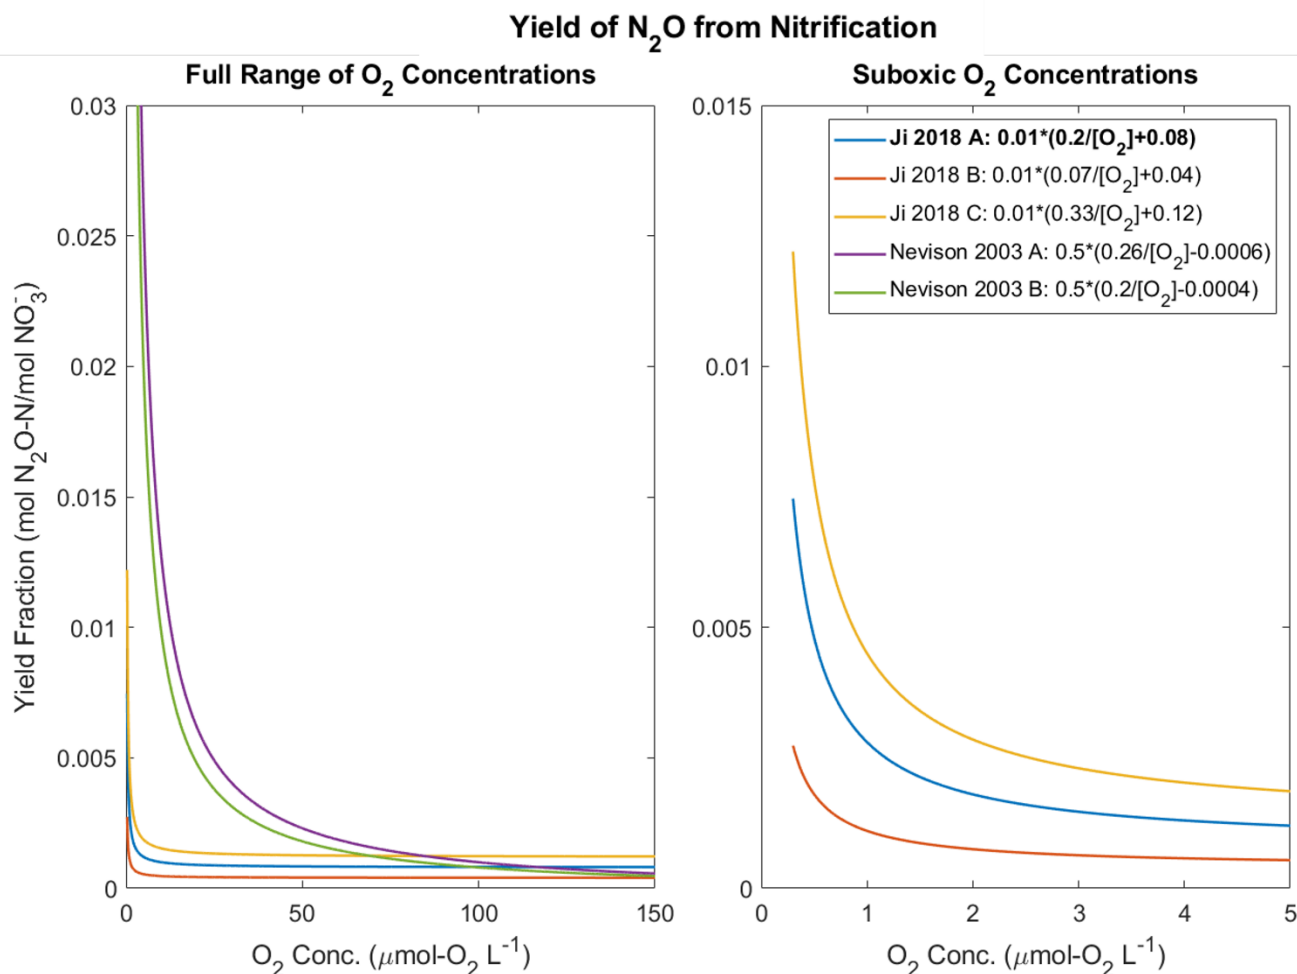

### 3.5.2 Nitrification N<sub>2</sub>O Yield Parameterization

Another key parameterization is the yield of N<sub>2</sub>O from nitrification. The equation representing this, *Equation 6*, was introduced by Nevison et al. (2003) and was further developed by Ji et al. (2015, 2018) – however, the parameterization itself is functionally the same. To understand how these changes in constants might affect N<sub>2</sub>O production by nitrification, different combinations of *a* and *b* were input into the model to determine the effects on nitrification N<sub>2</sub>O production.

**Table 5:** Parameterizations for N<sub>2</sub>O yield from nitrification ( $\gamma$ )

Yield Formula	<i>a</i> and <i>b</i> constants
(Nevison et al. 2003): $\gamma = 0.5(a/[O_2] + b)$	
Nevison et al. parameterization A	$a = 0.26 \mu\text{mol-O}_2 \text{ L}^{-1}$ , $b = -0.0006$
Nevison et al. parameterization B	$a = 0.20 \mu\text{mol-O}_2 \text{ L}^{-1}$ , $b = -0.0004$
(Ji et al. 2015, 2018): $\gamma = 0.01(a/[O_2] + b)$	
Ji et al. parameterization A (base case scenario)	$a = 0.20 \mu\text{mol-O}_2 \text{ L}^{-1}$ , $b = 0.08$
Ji et al. parameterization B	$a = 0.07 \mu\text{mol-O}_2 \text{ L}^{-1}$ , $b = 0.04$
Ji et al. parameterization C	$a = 0.33 \mu\text{mol-O}_2 \text{ L}^{-1}$ , $b = 0.12$

Applying these parameterizations across a range of O<sub>2</sub> concentrations gives the results shown in Figure 44. The main differences between Nevison et al. (2003) and Ji et al. (2015, 2018)'s formulations are that Nevison parameterization are more sensitive to O<sub>2</sub> at higher concentrations, and that the maximum yield at suboxic concentrations is much higher than in the Ji parameterization (Figure 44). This is likely because Nevison et al. (2003) based their research off laboratory studies conducted by Goreau et al. (1980) that produced higher N<sub>2</sub>O yields from nitrification than the in-situ studies conducted by Ji et al. (2015, 2018). The more recent research by Ji et al. (2015, 2018) included *in situ* studies that show a much lower yield of N<sub>2</sub>O by nitrification than the laboratory culture studies by Goreau et al. (1980) that were used for Nevison et al. (2003)'s original yield parameterization. Therefore, while it was important to compare Ji et al. (2015, 2018)'s parameterizations with the parameterizations by Nevison et al. (2003), the newer version was taken as the more reasonable scenario. The base case of  $a = 0.2 \mu\text{mol-O}_2 \text{ L}^{-1}$ ,  $b = 0.08$  is based on the recommendation by Ji et al. (2018).

**Figure 44:** Yield of N<sub>2</sub>O from nitrification ( $\gamma$ ) with different parameterizations across a range of O<sub>2</sub> concentrations. Left panel shows a wider range of O<sub>2</sub> concentrations and all five yield parameterizations, while the right panel shows suboxic O<sub>2</sub> concentrations and highlights differences between the different Ji et al. (2018) parameter estimates. Base case scenario (Ji 2018 A) is in bold.

From Figure 44 it is obvious that the amount of N<sub>2</sub>O by nitrification will be greatly affected by the parameterization choice. Previous studies have reported a wide range of global nitrification N<sub>2</sub>O production rates and these estimates tend to be much higher than those produced by this model (see Table 1; also discussed further in Section 4.2). However, most of these models have not implemented the newer Ji et al. (2015, 2018) parameterizations that would substantially decrease the yield of N<sub>2</sub>O by nitrification in the higher O<sub>2</sub> concentration range and so decrease the global nitrification N<sub>2</sub>O production rate. When compounded with the higher denitrification N<sub>2</sub>O production rates generated by newer and more accurate O<sub>2</sub> data products (see Section 3.3), this would result in the much smaller proportions of N<sub>2</sub>O produced by nitrification than by denitrification seen in this model in comparison to past estimates.

To see how strongly the yield parameterization affects global N<sub>2</sub>O production rates from nitrification, the combinations listed above were compared using model output of global nitrification production rate estimates (Figure 45). The substantial difference in yield parameterizations in Figure 44 (left) is also seen in Figure 45, where the range of global nitrification N<sub>2</sub>O production rates can differ by up to 74.1%. Despite this large difference in

nitrification  $\text{N}_2\text{O}$  production, the relatively small influence of nitrification production rates compared to denitrification production and consumption rates means that the effect from different yield parameterizations has a low effect on the global net  $\text{N}_2\text{O}$  production rate. For perspective, the difference between the smallest (Ji 2018 B) and largest (Nevison 2003 A) global nitrification  $\text{N}_2\text{O}$  production rates amounts to a maximum 8.4% difference in global *net*  $\text{N}_2\text{O}$  production rates (Figure 46).

**Figure 45:** Global  $\text{N}_2\text{O}$  production rates by nitrification with different parameterizations for yield ( $\gamma$ ) of  $\text{N}_2\text{O}$  from nitrification. Base case scenario (Ji 2018 A) is in bold.

Nitrification  $\text{N}_2\text{O}$  production rates are greatly increased when using the Nevison et al. (2003) formulation, which is understandable given the overall higher yield of  $\text{N}_2\text{O}$  by nitrification by this parameterization (Figure 44). Notably, the Nevison parameterization “B” was comparable to the Ji parameterization “C”, implying that even using the older Nevison yield parameterization it may be possible to generate similar global  $\text{N}_2\text{O}$  production rates by nitrification. However, even with the higher yields by the Nevison parameterizations the global  $\text{N}_2\text{O}$  production rates by nitrification are still lower than most past estimates (Figure 46).

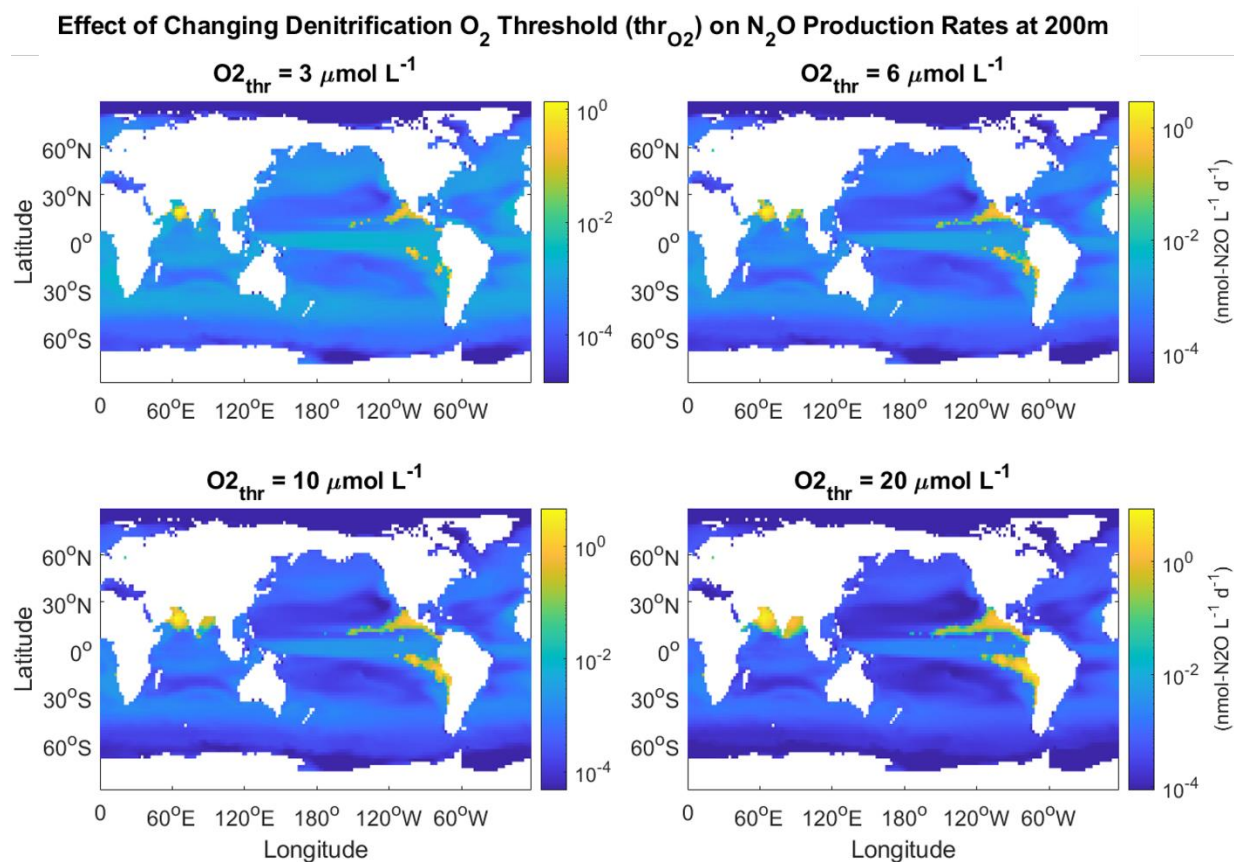

**Figure 46:** Global N<sub>2</sub>O production rates with varying parameterizations for yield ( $Y$ ) of N<sub>2</sub>O from nitrification. Base case scenario (Ji 2018 A) is in bold.

The yield parameterization is notable in that it is one of the few parameters that affects the proportion of global N<sub>2</sub>O production rates by nitrification substantially enough to affect global net N<sub>2</sub>O production rates. However, different parameterizations still produce relatively low N<sub>2</sub>O production rates by nitrification relative to denitrification.

This is reasonable in the scope of our model – while nitrification production of N<sub>2</sub>O is mostly determined by the yield of nitrification to N<sub>2</sub>O instead of NO<sub>3</sub><sup>-</sup>, it is also reliant on the nitrification rates themselves which are in turn directly reliant on organic matter input from detritus remineralization rates. This, combined with O<sub>2</sub> limitations from  $fO_{2,AmOx}$ , means that low nitrification N<sub>2</sub>O production rates are only moderately influenced by changes in the yield parameterization.

### 3.5.3 O<sub>2</sub> Threshold for Oxidic vs. Suboxic Remineralization

The proportion of suboxic remineralization (denitrification) is controlled by availability of O<sub>2</sub>. The commonly cited O<sub>2</sub> threshold at which oxidic remineralization ends and suboxic remineralization begins has been widely debated due to discrepancies between model, laboratory, and in-situ research (Paulmier and Ruiz-Pino 2009, Bianchi et al. 2012, Babbin et al. 2015, Sun et al. 2021). The commonly used 6 μmol-O<sub>2</sub> L<sup>-1</sup> threshold is maintained as the base case in this model – however, a sensitivity experiment was conducted to highlight how additional research on this threshold could improve models. In this experiment, the O<sub>2</sub> threshold,  $thr_{O_2}$ , was varied between 3, 6, 10, and 20 μmol-O<sub>2</sub> L<sup>-1</sup>.

**Figure 47:** Effect of  $O_2$  concentration threshold for denitrification ( $thr_{O_2}$ ) on global net  $N_2O$  production rates at 200 m.

The  $O_2$  threshold for suboxic remineralization affects the amount of  $N_2O$  from denitrification production and consumption, which is shown in Figure 47 for a depth of 200 m. The hotspots of high production rates that occur in ODZs increase in size with increasing  $thr_{O_2}$ . This affects the global total  $N_2O$  production rate very strongly as the volume of water with  $N_2O$  production by denitrification expands.

**Figure 48:** Global N<sub>2</sub>O production rates with varying  $thr_{O_2}$ . Base case scenario ( $thr_{O_2} = 6 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) is in bold.

As it is often common practice to use  $6 \mu\text{mol-O}_2 \text{ L}^{-1}$  for  $thr_{O_2}$ , a much higher threshold of  $20 \mu\text{mol-O}_2 \text{ L}^{-1}$  seems unlikely despite its use in some models (Sun et al. 2021). This is highlighted by the high global N<sub>2</sub>O production rates seen in Figure 48. However, if true it would have important repercussions for the global nitrogen budget and can increase net N<sub>2</sub>O production rates by over ten times.

### 3.5.4 Exponent $c$ in $\Omega$

As with changes in  $thr_{O_2}$ , the exponent  $c$  in the partitioning term between oxic and suboxic remineralization ( $\Omega$ ) also affects the proportion of N<sub>2</sub>O production from denitrification. Increasing  $c$  results in smaller denitrification (and associated production and consumption of N<sub>2</sub>O) rates. As  $\Omega$  is a term created for this model,  $c$  does not have any literature values to compare – instead, the base case scenario where  $c = 3$  was chosen to approximate observed relationships between denitrification rate and O<sub>2</sub> (e.g., Devol 1978, Dalsgaard et al. 2012). Figure 49, below, shows how varying  $c$  affects the proportion of oxic remineralization in relation to denitrification.

**Figure 49:** Fraction of oxidic respiration (1-Ω) with varying exponent  $c$ . Base case scenario ( $c = 3$ ) is in bold.

When  $c > 1$ , the oxidic respiration curve has high oxidic respiration at the upper end of suboxic concentrations (3-6 μmol-O<sub>2</sub> L<sup>-1</sup>), which is what best represents the trends shown by Devol (1978) and Dalsgaard et al. (2012) in their laboratory experiments on bacterial oxygen uptake kinetics in ODZs. When  $c < 1$  the opposite is true – oxidic respiration rapidly declines, even at O<sub>2</sub> concentrations near the  $thr_{O_2}$  of 6 μmol-O<sub>2</sub> L<sup>-1</sup>, which is not consistent with existing literature. Because of this, this model uses only values  $> 1$  (Figure 49). A higher  $c$  implies that the fraction of oxidic respiration remains high for a wider range of the upper suboxic O<sub>2</sub> concentrations.

The effect of changing  $c$  on net  $\text{N}_2\text{O}$  production rates can be seen using a depth profile in the North Pacific ODZ (Figure 50). As  $c$  increases, net denitrification  $\text{N}_2\text{O}$  production rates (denitrification production minus consumption) decrease.

**Figure 50:** Effect of changing exponent  $c$  on net  $\text{N}_2\text{O}$  production rates by denitrification in the North Pacific ODZ at  $17^\circ\text{N}$ ,  $114^\circ\text{W}$ . Base case scenario ( $c = 3$ ) is in bold.

This is also reflected in the global  $\text{N}_2\text{O}$  production rates (Figure 51); however, the strong difference seen in the ODZ is diminished in global totals due to the relatively small region ODZs occupy in the global ocean.

**Figure 51:** Effect of varying exponent  $c$  in  $\Omega$  on global N<sub>2</sub>O production rates. Base case scenario ( $c = 3$ ) is in bold.

Although  $c$  does have substantial influence over the global net N<sub>2</sub>O production rates through control of global denitrification production and consumption rates, it is not as strong as the influence of  $thr_{O_2}$ . A smaller  $c$  of 1.5 generates larger net N<sub>2</sub>O production rates of 20.5 Tg-N y<sup>-1</sup> while a larger  $c$  of 6 generates smaller net N<sub>2</sub>O production rates of 6.4 Tg-N y<sup>-1</sup> – less than a third of rates produced by  $c = 1.5$ . The base case scenario,  $c = 3$ , leads to net N<sub>2</sub>O production rates of 11.5 Tg-N y<sup>-1</sup> and was selected mainly due to its ‘middling’ status. Lowering the value of  $c$  can result in net N<sub>2</sub>O production rates that increase over three times from the lowest to highest tested values.

As  $\Omega$  itself is a newly introduced term and involves both these parameters, the combination of both  $thr_{O_2}$  and  $c$  will have a strong effect on how global N<sub>2</sub>O production rates are calculated. These two quantities are highly influential to N<sub>2</sub>O production rates as well as highly uncertain and require more quantification in both laboratory and *in situ* studies.

### 3.5.5 Denitrification Consumption O<sub>2</sub> Inhibition Term ( $K_{O_2,cons}$ )

While the first step of denitrification (production of N<sub>2</sub>O by reducing NO<sub>3</sub><sup>-</sup>) begins at 6 μmol-O<sub>2</sub> L<sup>-1</sup>, the second step (consumption of N<sub>2</sub>O by reducing N<sub>2</sub>O to N<sub>2</sub>) largely occurs at much lower O<sub>2</sub> concentrations. The exact concentration and the relationship between N<sub>2</sub>O consumption rates by denitrification with O<sub>2</sub> are not well understood, mainly due to these two steps being combined in modelling studies and the difficulty of measuring reactions in extremely low O<sub>2</sub> waters in observational and laboratory studies.

The parameterization used in this model uses a rate constant, N<sub>2</sub>O concentration, and an exponential relationship with O<sub>2</sub> according to an O<sub>2</sub> ‘poisoning’ term (Equation 10). The exponential parameterization means  $K_{O_2,cons}$  is not a ‘hard’ O<sub>2</sub> threshold like  $thr_{O_2}$  in  $\Omega$

(partitioning between oxic and suboxic remineralization), but still reflects the near-anoxic  $O_2$  concentrations required for reduction of  $N_2O$ .

To see how  $K_{O_2,cons}$  affects the relationship between  $N_2O$  consumption and production by denitrification, as well as total global  $N_2O$  production rates,  $K_{O_2,cons}$  was varied between 0.3, 1.0, 3.0, and 4.5  $\mu\text{mol-O}_2 \text{ L}^{-1}$  (Figure 52). This allows investigation into denitrification consumption only occurring in anoxic environments as well as in environments where  $O_2$  concentrations are much higher.

**Figure 52:** Effect of varying  $K_{O_2,cons}$  on  $N_2O$  consumption within suboxic range of  $O_2$  concentrations. Base case scenario ( $K_{O_2,cons} = 0.3 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) is in bold.

The base case scenario,  $K_{O_2,cons} = 0.3 \mu\text{mol-O}_2 \text{ L}^{-1}$  (blue), demonstrates how  $N_2O$  consumption begins at below approximately  $2 \mu\text{mol-O}_2 \text{ L}^{-1}$  but is limited except at  $\ll 1 \mu\text{mol-O}_2 \text{ L}^{-1}$ . When  $K_{O_2,cons}$  is lower than this,  $N_2O$  consumption will remain very low even when  $O_2$  is less than  $0.5 \mu\text{mol-O}_2 \text{ L}^{-1}$ .

When  $K_{O_2,cons}$  is higher than  $0.3 \mu\text{mol-O}_2 \text{ L}^{-1}$ ,  $N_2O$  consumption begins at higher  $O_2$  concentrations. Even increasing  $K_{O_2,cons}$  to  $1.0 \mu\text{mol-O}_2 \text{ L}^{-1}$  (red) causes  $N_2O$  consumption near the  $thr_{O_2}$  of  $6 \mu\text{mol-O}_2 \text{ L}^{-1}$ , while a  $K_{O_2,cons}$  higher than  $3.0 \mu\text{mol-O}_2 \text{ L}^{-1}$  (yellow, purple) results in  $N_2O$  consumption occurring outside the suboxic region, which is not plausible.

**Figure 53:** Global  $\text{N}_2\text{O}$  production rates with varying  $K_{O_2,cons}$  for  $\text{N}_2\text{O}$  consumption by denitrification. Base case scenario ( $K_{O_2,cons} = 0.3 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) is in bold

Figure 53 shows  $\text{N}_2\text{O}$  consumption and production by denitrification by using varying  $K_{O_2,cons}$  to generate global  $\text{N}_2\text{O}$  production rates. Nitrification and denitrification production rates are unaltered by changes in  $K_{O_2,cons}$ , but the net  $\text{N}_2\text{O}$  production rates are substantially affected. The large amount of  $\text{N}_2\text{O}$  produced by denitrification causes strong  $\text{N}_2\text{O}$  consumption rates, with higher  $K_{O_2,cons}$  creating higher  $\text{N}_2\text{O}$  consumption rates – varying  $K_{O_2,cons}$  between 0.3 and 4.5  $\mu\text{mol-O}_2 \text{ L}^{-1}$  can lead to consumption rates between 8.4 and 13.9  $\text{Tg-N y}^{-1}$  (maximum 40% difference), with the lower consumption rate a result of a lower  $K_{O_2,cons}$ . This is reflected in the net  $\text{N}_2\text{O}$  production rates, as a low  $K_{O_2,cons}$  and low consumption rate will lead to increased net  $\text{N}_2\text{O}$  production when  $\text{N}_2\text{O}$  production rates remain the same.

The strong correlation between global net  $\text{N}_2\text{O}$  production rates and  $K_{O_2,cons}$  combined with the uncertainty of the nature of the consumption pathway – i.e., the  $\text{O}_2$  concentration at which it begins and the shape of the curve as  $\text{O}_2$  changes – implies that this quantity is one of the more important parameters to be investigated by future research. Gaining more information on  $K_{O_2,cons}$  and the best form of  $\text{N}_2\text{O}$  consumption rate parameterization will be of paramount importance in determining the proportions of global  $\text{N}_2\text{O}$  produced and consumed by the three pathways.

### 3.6 Effects of Projected Future Climate Change

The five global Earth System models (ESMs) discussed above (CanESM5, CanESM5-CanOE, CNRM-ESM2-1, GFDL-ESM4, UKESM1-0-LL) are used in this section to provide historical and future estimates of  $\text{O}_2$ , detritus flux, and temperature. Historical data are averages for 1986-2005, whereas future data are averages for 2081-2100. The *delta* data are created by taking the projected future minus historical data from the five ESMs and, in the case of  $\Delta\text{O}_2$ , adding this to

the present-day data from the World Ocean Atlas. The intent here is to determine whether any changes in global N<sub>2</sub>O production rates using varying data product inputs are a result of differences between models or differences between past and future data. As the five ESMs use different parameterizations to generate data, changes in the magnitude and spatial resolution of the data products can be better compared from historical to future projections when accounting for the differences in the model. For example, if a certain model consistently predicts lower O<sub>2</sub> concentrations than the others, it might look as if the amount of deoxygenation in future projections is also stronger for this model than for the other ESMs. However, by using the delta data only the *difference* between past and future is compared between models – since that specific model has lower O<sub>2</sub> for both past and future, the delta data may show that the amount of O<sub>2</sub> loss projected for the future is in fact weaker than for the other ESMs.

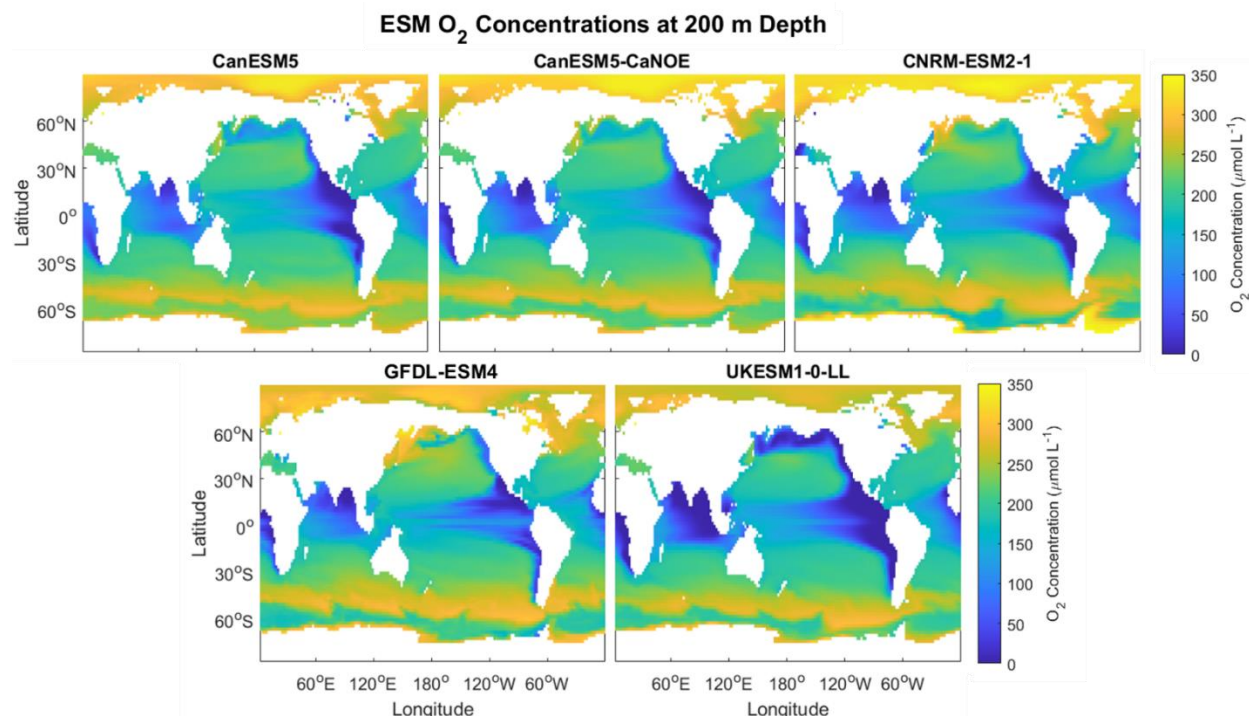

In all tested scenarios, ESM EPC or temperature was input to the model for historical simulations and future projections, so that the final result is the model output of future projections of N<sub>2</sub>O production and consumption rates minus the historical projections of N<sub>2</sub>O production and consumption rates. For O<sub>2</sub>, the difference of historical and projected O<sub>2</sub> (delta) was added to the WOA O<sub>2</sub> data ( $\Delta O_2 + O_{2,WOA}$ ) to better compare global N<sub>2</sub>O production and consumption rates to the base case scenario. Adding the delta data to the WOA data is necessary for O<sub>2</sub> due to biases in the ESM distribution of O<sub>2</sub>.

### 3.6.1 Oxygen

To analyze how global N<sub>2</sub>O production rates will be affected by future changes in O<sub>2</sub>, namely anticipated global deoxygenation due to anthropogenic influences, O<sub>2</sub> data from the five ESMs is input into the model – this includes O<sub>2</sub> for the historical climate, for the future climate, as well as delta O<sub>2</sub> (future minus historical data products) added to the observation-based base case.

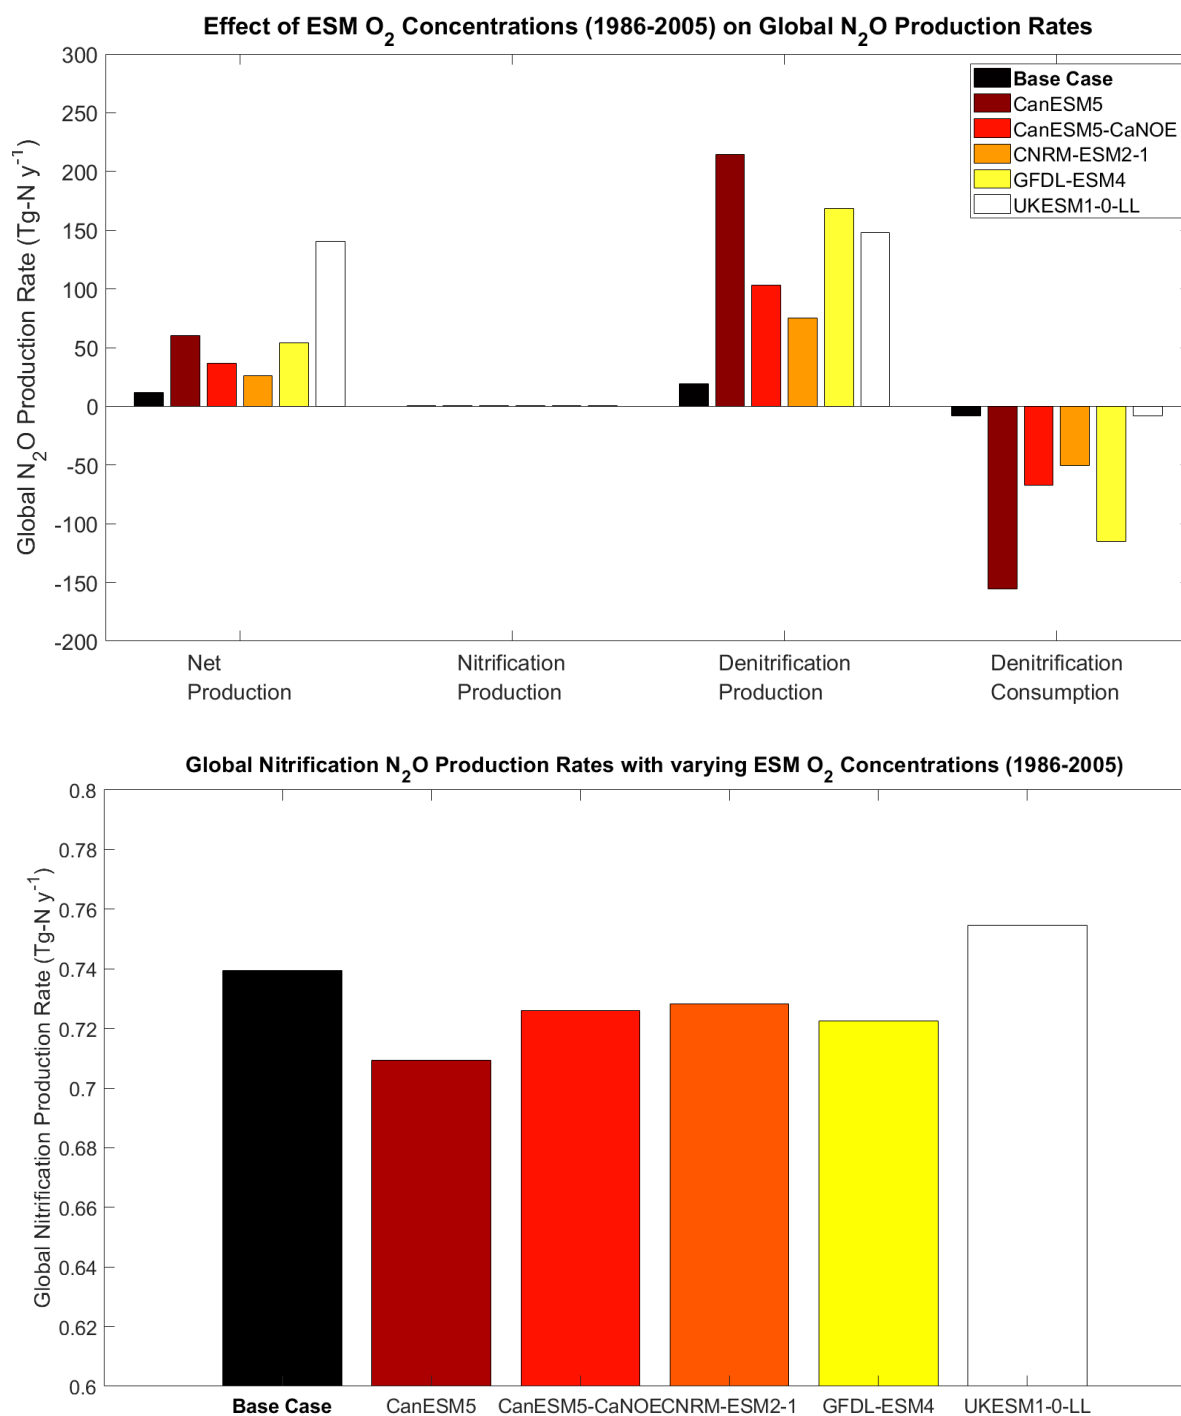

#### Historical O<sub>2</sub> Data

The historical O<sub>2</sub> data generated by the five ESMs (as opposed to the 2018 World Ocean Atlas data used in the base case scenario of the model) have varying spatial distributions as depicted in Figure 54. The size and intensity of the ODZs in the eastern North Pacific, eastern South Pacific, and the Arabian Sea are of particular importance as they strongly influence the amount of N<sub>2</sub>O produced and consumed by denitrification in suboxic waters.

**Figure 54:** Historical (1986-2005) ESM O<sub>2</sub> concentrations at 200 m depth.

Applying these data products to the model produces rates of N<sub>2</sub>O production and consumption shown in Figure 55 (top: all production and consumption pathways, bottom: nitrification production rates from top panel depicted at a larger scale). Figure 55 (top) displays how global net N<sub>2</sub>O production rates vary using the five different O<sub>2</sub> model data products from 1986-2005 as well as the base case scenario for this model using O<sub>2</sub> data products from the 2018 World Ocean Atlas.

**Figure 55:** Effect of O<sub>2</sub> distribution from five ESMs on global N<sub>2</sub>O production and consumption rates

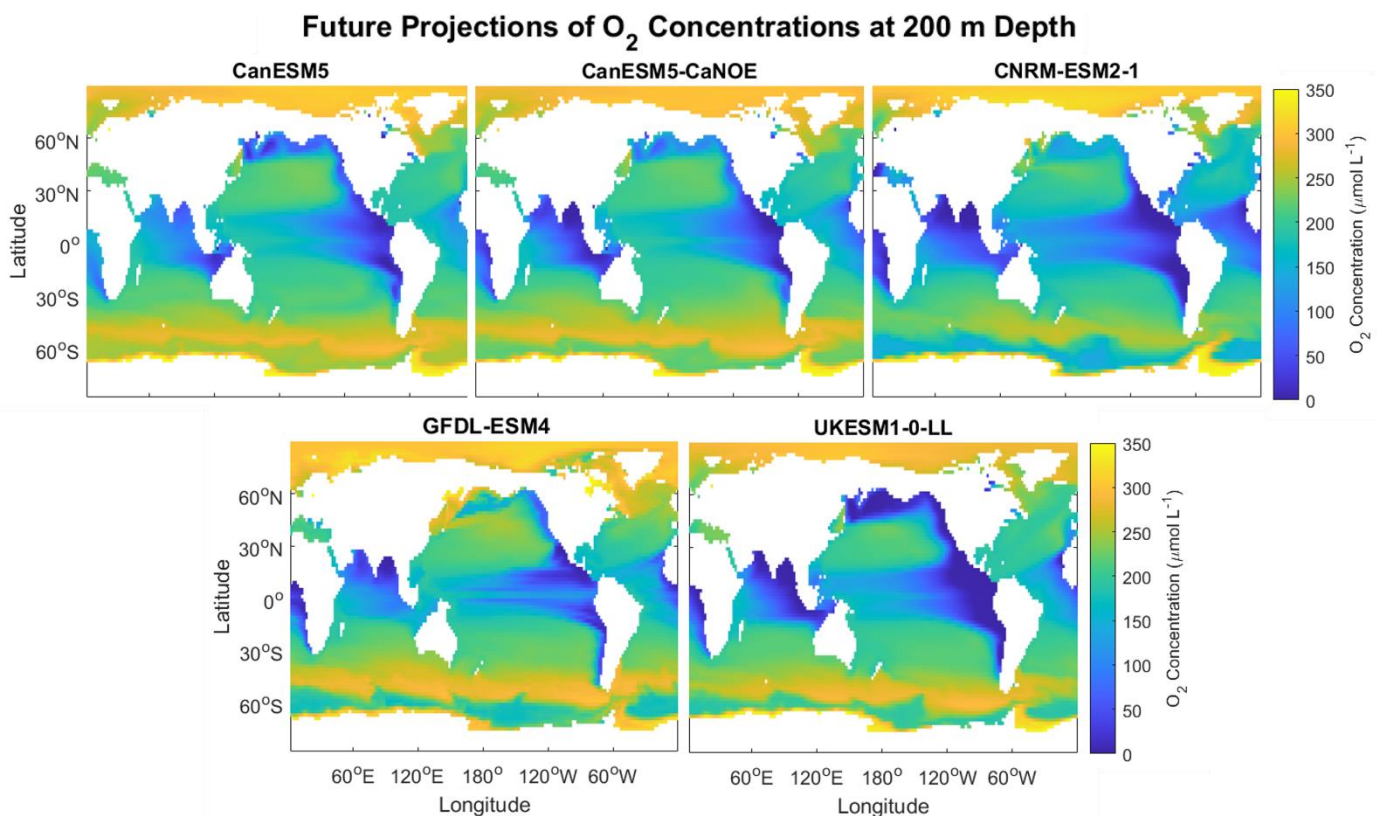

The first notable difference in using ESM O<sub>2</sub> data, rather than the base case scenario of using WOA data, is a substantial increase in net N<sub>2</sub>O production rates due to a large increase in denitrification N<sub>2</sub>O production and consumption rates (Figure 55, top) that is not seen in the nitrification N<sub>2</sub>O production rates (Figure 55, bottom). Nitrification production rates for the base

case are slightly higher than the average of all five ESMs, though lower than the highest  $\text{N}_2\text{O}$  production rates by nitrification for UKESM1-0-LL. Denitrification production rates also remain higher than denitrification consumption rates, especially in the case of the UKESM1-0-LL data – net  $\text{N}_2\text{O}$  production rates are over twice as large as for the other ESMs because denitrification consumption rates are extremely low. Conversely, CanESM5 has high denitrification production rates but also has high denitrification consumption rates. Because of this, the net  $\text{N}_2\text{O}$  production rates for CanESM5 are substantially lower than UKESM1-0-LL despite having much larger  $\text{N}_2\text{O}$  production rates by denitrification.

Both CanESM5 and UKESM1-0-LL have the largest net  $\text{N}_2\text{O}$  production rates by denitrification, but the difference lies in the magnitude of the production and consumption rates by denitrification. UKESM1-0-LL has more denitrification production occurring without simultaneous denitrification consumption that would lower the net  $\text{N}_2\text{O}$  production rates. In comparison, CanESM5 has global denitrification production rates that are larger than for UKESM1-0-LL but has substantial denitrification consumption rates that lower the net  $\text{N}_2\text{O}$  production rates (discussed further in Discussion, Section 4.1).

### Future Projections of $\text{O}_2$

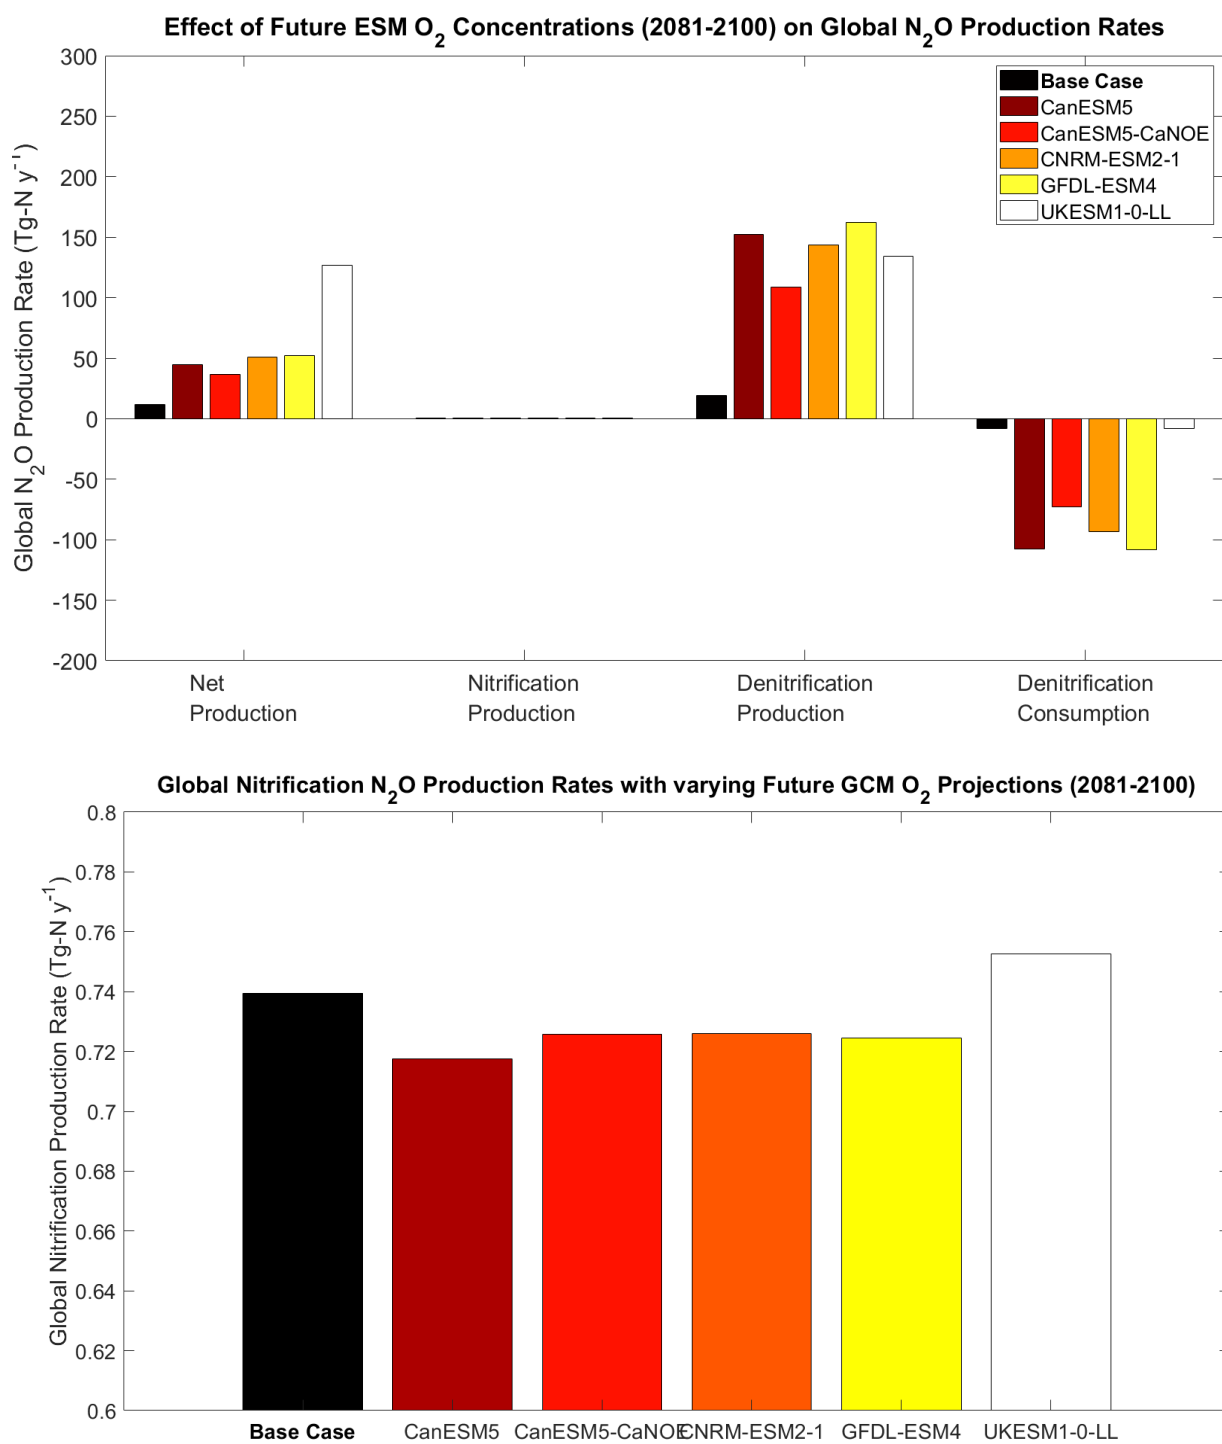

Global maps of the future projections of  $\text{O}_2$  data at 200 m from the five ESMs is depicted in Figure 56. Visually, there is very little difference between future and historical  $\text{O}_2$  projections, but slight variation results in different global  $\text{N}_2\text{O}$  production rates, as shown in Figure 56.

**Figure 56:** Future ESM Projections of  $\text{O}_2$  at 200 m depth.

Global  $\text{N}_2\text{O}$  production rates using future projections of  $\text{O}_2$  from the five ESMs (Figure 57) show that differences among models are somewhat maintained, e.g., UKESM1-0-LL remains the

highest due to low denitrification consumption rates. Top panel depicts all production and consumption processes, while bottom panel highlights the nitrification production rates from the top panel at a larger scale.

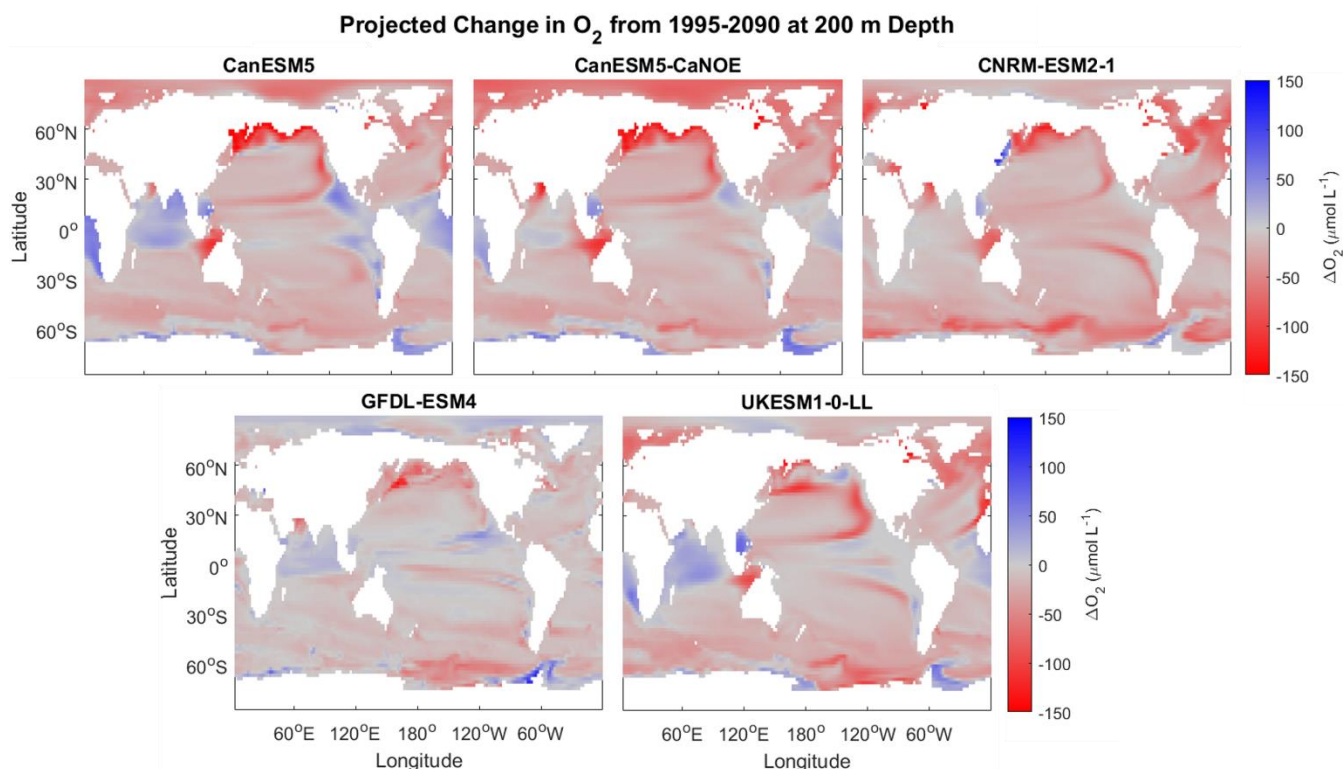

**Figure 57:** Global N<sub>2</sub>O production and consumption rates based on future (2081-2100) O<sub>2</sub> concentrations from five ESMs.

Incorporating future  $O_2$  data results in UKESM1-0-LL having the highest  $N_2O$  production rates by far, over twice the magnitude of any other ESM, due to extremely low  $N_2O$  consumption rates. The other four models are comparable in their net  $N_2O$  production rates, with CanESM5-CaNOE having the lowest net production rates. Interestingly, while both CanESM5 and GFDL-ESM4 have similar denitrification production and consumption rates that are larger than those of CNRM-ESM2-1, CNRM-ESM2-1's net  $N_2O$  production rates are of near-equal magnitude to CanESM5 and GFDL-ESM4. This means that the net denitrification production rate (denitrification production minus consumption) is comparable for all three models despite differences in the magnitudes of denitrification production and consumption. Nitrification  $N_2O$  production rates are comparable across all ESMs, though UKESM1-0-LL has slightly higher rates. The base case scenario has nitrification rates close to an average between the UKESM1-0-LL and four other ESMs.

### $\Delta O_2$ : Future Minus Historical $O_2$

The  $\Delta O_2$  (future minus historical from the five ESMs) is investigated here to assess projected future changes in  $N_2O$  production and consumption rates independently of model bias and to compare the magnitude of that future change with the model bias in the historical data. A visual representation of  $\Delta O_2$  is provided in Figure 58, where red indicates regions where  $O_2$  decreases from historical to future (deoxygenation).

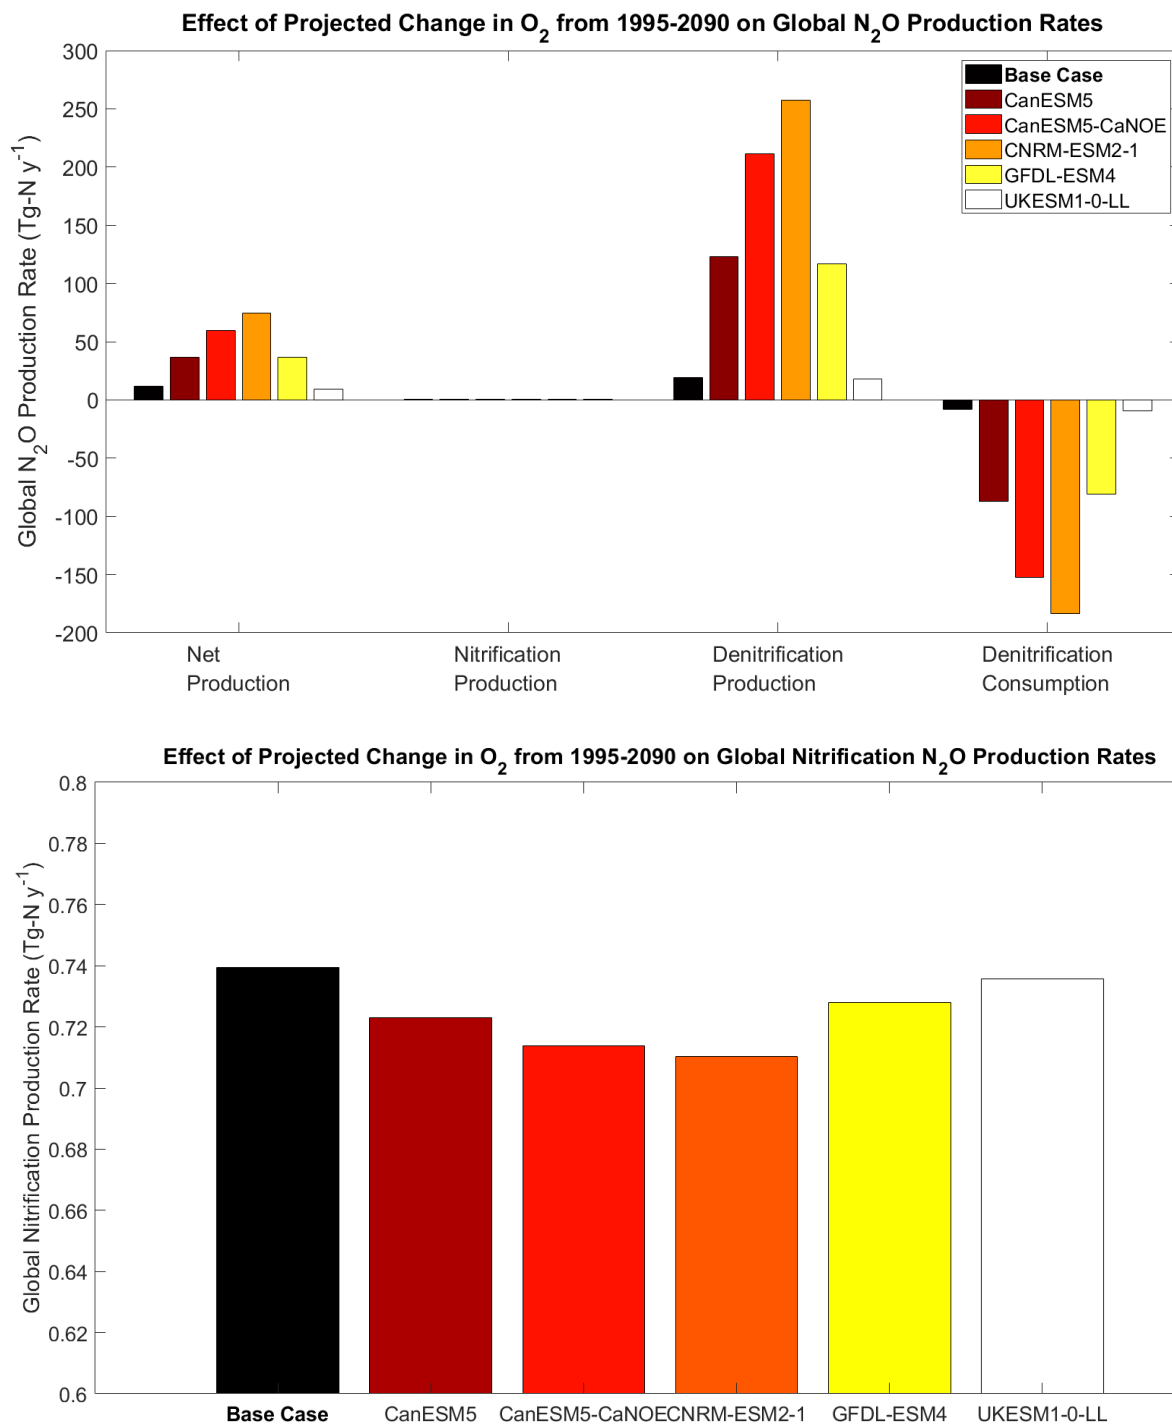

**Figure 58:** Projected change in  $O_2$  ( $\Delta O_2$ : future minus historical  $O_2$  concentration) from 1986-2090 for each of the five ESMs from the ssp585 experiment at 200 m.

Interestingly, while the boundaries of ODZs in the North and South Pacific tend to experience a decrease in  $O_2$ , the ODZ cores experience an increase in  $O_2$  for some of the ESMs (Figure 58). As  $N_2O$  production and consumption by denitrification increase from past to future (Figure 59, top panel), the expansion of ODZ regions seems to have a greater effect on  $N_2O$  than locally

increased  $O_2$ . There are multiple possible explanations for this. The ODZ region may expand, increasing the global volume of suboxic water and leading to more denitrification production of  $N_2O$ . Similarly, decreased  $O_2$  in ODZs may increase denitrification production rates (as well as consumption rates), and could increase yield of  $N_2O$  from nitrification. Increased  $O_2$  in the core of ODZs also decreases  $N_2O$  consumption, leading to a higher proportion of  $N_2O$  produced by denitrification versus  $N_2O$  consumed by denitrification. Denitrification production is similarly decreased with increased  $O_2$ , but the range of  $O_2$  that permits denitrification production is larger than the range required for denitrification consumption, so elevated  $O_2$  in ODZ cores still supports some denitrification production of  $N_2O$  while inhibiting consumption.

It is not clear which of these scenarios has the greatest effect on net  $N_2O$  production rates in these regions, but their net effect for each ESM is shown in Figure 59.  $\Delta O_2$  in the oxygenated waters has a minimal effect on nitrification  $N_2O$  production rates - as long as  $O_2$  is above approximately  $50 \mu\text{mol-}O_2 \text{ L}^{-1}$ , neither nitrification rate nor nitrification  $N_2O$  yield will change substantially (see Figures 8-9, Section 2.1.1). Figure 59 provides a better look at how changing  $O_2$  may affect  $N_2O$  production, where  $\Delta O_2$  from the future and historical ESM data products is added to the original WOA  $O_2$  data product and input into the model.

**Figure 59:** Global  $N_2O$  production and consumption rates  $\Delta O_2$  (future minus historical  $O_2$ ) concentrations for five ESMs from the ssp585 experiment, where  $\Delta O_2$  is added to the base case  $O_2$  data from World Ocean Atlas 2018.

With the exception of UKESM1-0-LL, global net  $N_2O$  production rates are much higher than in the base case of  $11.5 \text{ Tg-N y}^{-1}$ . Since  $O_2$  input into the model uses WOA data plus the ESMs'  $\Delta O_2$ , this means that the  $\Delta O_2$  decreases the  $O_2$  strongly enough from past to future to greatly increase denitrification production and consumption rates. In other words, while there is some spatial variation among the ESMs that results in varying  $N_2O$  production and consumption, the

overall change between past and future produces a substantial increase in global net N<sub>2</sub>O production rates. This change is due to larger denitrification net N<sub>2</sub>O production rates: both denitrification production and consumption rates increase, but denitrification production rates remain higher than consumption rates.

While UKESM1-0-LL displayed high denitrification production rates and very low denitrification consumption rates in both historical and future data, this effect is mitigated in the  $\Delta O_2$  data. Essentially, the change between past and future O<sub>2</sub> for UKESM1-0-LL results in the smallest change in global N<sub>2</sub>O production and consumption rates such that net global N<sub>2</sub>O production rates are similar to the base case scenario that uses historical WOA data. This likely means that the extremely low denitrification consumption rates for UKESM1-0-LL is due to model bias, as it isn't reflective in the  $\Delta O_2$  data.

Conversely, CanESM5-CanOE and CNRM-ESM2-1 have very large changes in global N<sub>2</sub>O production and consumption rates by denitrification to result in very high net N<sub>2</sub>O production rates in comparison to the base case scenario. Both CanESM5 and GFDL-ESM4 see more moderate increases in net N<sub>2</sub>O production rates, and UKESM1-0-LL sees very little change from past to future N<sub>2</sub>O production rates.

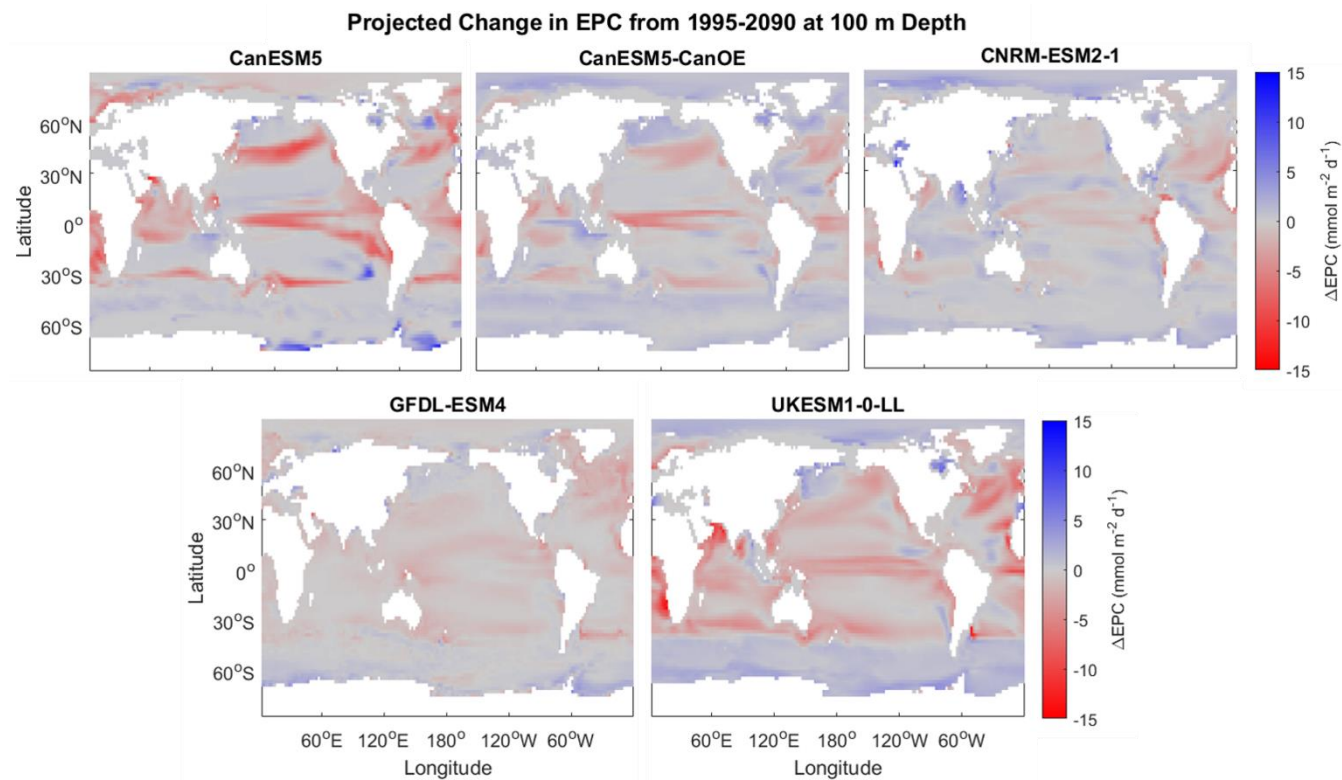

Nitrification production rates are not substantially affected by  $\Delta O_2$ , which is reasonable given that nitrification is much less sensitive to changes in O<sub>2</sub> than denitrification. Nevertheless, there is a small decrease in nitrification production rates across all ESMs in comparison to the base case scenario.

### 3.6.2 Organic Matter Flux

Organic matter input to the model will also be analyzed by comparing historical and future projections of EPC – export of particulate carbon at 100 m – from the five ESMs by using the  $\Delta EPC$  (Figure 62). Unlike the above section with  $\Delta O_2$ , where the  $\Delta O_2$  is added to the base case historical 2018 WOA data, the  $\Delta EPC$  will not be added to the base case scenario. The organic matter (detritus) input for the base case scenario of the model uses historical EPC from CanESM5-CanOE, where a comparison of global N<sub>2</sub>O production rates across the five ESMs for the historical EPC was presented in Section 3.3.1 (Figure 31). Historical EPC is normalized to 20 Pg-C y<sup>-1</sup> as in the base case scenario, and the adjustment factor used for each model's historical EPC normalization is then applied to the future EPC projections for each ESM.

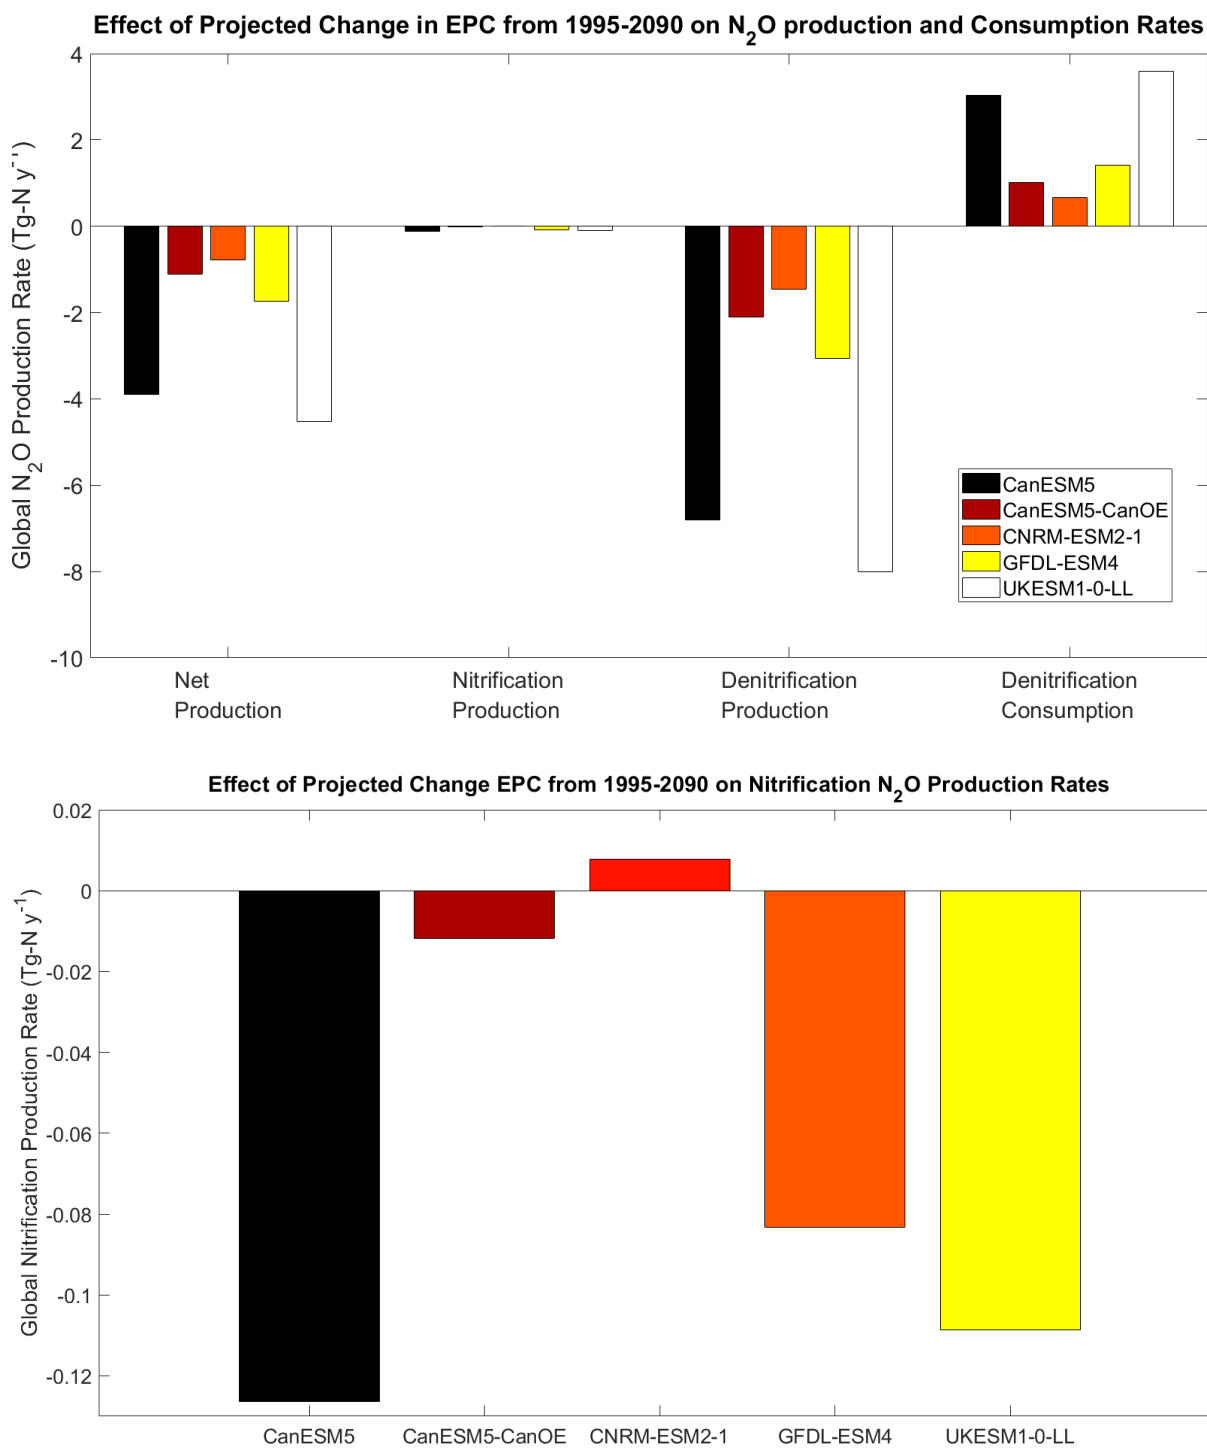

### $\Delta$ EPC: Future Minus Historical Data Products

$\Delta$ EPC in this section involves the future minus historical data (Figures 60, 61).  $\Delta$ EPC provides valuable information on how strongly the spatial patterns between ESMs may affect global  $N_2O$  production and consumption rates compared to the changes over time.

**Figure 60:** Change in EPC from 1995-2090 ( $\Delta$ EPC: future minus historical) for each of the five ESMs at 100 m depth from the ssp585 experiment.

Compared to the maps for  $\Delta O_2$ , the  $\Delta EPC$  at 200 m in Figure 60 depicts less variation from past to future data for all five ESMs. CanESM5 and UKESM1-0-LL experience the greatest changes in EPC, especially in the Southern Ocean for CanESM5.

**Figure 61:** Changes in  $N_2O$  production and consumption rates due to changes in EPC ( $\Delta EPC$ : future minus historical) for five ESMs from the ssp585 experiment.

It is important to note that Figure 61 differs from the above analysis for  $O_2$  (Figure 59) in that the change in  $N_2O$  production and consumption rates is from future-minus-past EPC ( $\Delta EPC$ ) (Figure 61), while the change in  $N_2O$  production and consumption rates for  $O_2$  uses future-minus-past  $O_2$  added to the base case  $O_2$  data from World Ocean Atlas ( $\Delta O_2 + O_{2,WOA}$ ) (Figure 59).

Changes in EPC from past to future lead to a substantial decrease in  $N_2O$  production and consumption by denitrification, resulting in a net decrease in the global net  $N_2O$  production rate. This effect is strongest for CanESM5 and UKESM1-0-LL, while CanESM5-CanOE (base case scenario), CNRM-ESM2-1, and GFDL-ESM4 experience a more moderate effect. This is reasonable, given that changes in EPC are most apparent for CanESM5 and UKESM1-0-LL (Figure 60). Globally, there is a net decrease in EPC from past to future model projections, which leads to a decrease in the amount of organic matter supplied to the system. Nitrification is more directly affected by total organic matter supply and so is more sensitive to changes in total EPC than denitrification, whereas denitrification is more sensitive to the spatial pattern. As a result, nitrification  $N_2O$  production rates also see a strong decrease from past to future - with the exception of CNRM-ESM2-1, which sees a small increase in nitrification production of  $N_2O$ . As EPC from CanESM5-CanOE is used for the base case of the model, the moderate decrease in net  $N_2O$  production as a result of denitrification and the small decrease in  $N_2O$  production from nitrification are most reflective of the data used for this model.

A similar experiment was conducted for  $\Delta EPC$ , where both historical and future EPC were normalized to  $20 \text{ Pg-C y}^{-1}$ . This uniform normalization means there is no change from past to future in the global total EPC, although both methods can be used to compare spatial differences between models for  $\Delta EPC$ . The uniform normalization also leads to a decrease in net  $N_2O$  production that is less than half of the magnitude of the above version in Figure 60. Interestingly, using the uniform normalization  $\Delta EPC$  leads to a net *increase* in  $N_2O$  production by nitrification for all models except GFDL-ESM4. The effect on nitrification production rates by  $\Delta EPC$  is much stronger than for  $\Delta O_2$ , as nitrification is more sensitive to changes in organic matter supply than to changes in  $O_2$ . When using this method, CanESM5-CanOE (used in the base case model) and UKESM1-0-LL have the largest changes in net production due to decreased denitrification.

### 3.6.3 Temperature Increase

The base case scenario uses temperature from the 2018 World Ocean Atlas, but historical and future projection data can also be generated using the five ESMs. Using the same method as for  $\Delta O_2$ , the spatial differences between models as well as between future and historical temperatures are evaluated by using the  $\Delta T$  data added to the existing 2018 WOA T data (Figure 62).

**Figure 62:** Changes in N<sub>2</sub>O production and consumption rates from  $\Delta T$  (future minus historical temperature) for the five ESMs from the ssp585 experiment.

The effect of changing temperature from past to future is negligible when considering N<sub>2</sub>O production and consumption rates.  $\Delta T$  itself is fairly small in comparison to  $\Delta EPC$  and especially to  $\Delta O_2$ , but more importantly the effect of variations in temperature on net N<sub>2</sub>O production rates is minimal ( $<0.6 \text{ Tg-N y}^{-1}$ ). While warming of the oceans will likely have some effect on remineralization rates, it has very little effect on net global N<sub>2</sub>O production rates.

## 4 Discussion

---

The aim of this research is to quantify and parameterize the main controls on N<sub>2</sub>O production by nitrification and denitrification, and to determine how strongly model parameters and environmental conditions affect net global N<sub>2</sub>O production. The uncertainty of many of these parameters necessitated evaluation of a range of values from existing model and observational literature, and the above results have highlighted which uncertainties are most important to N<sub>2</sub>O production reactions. This section provides a discussion of these parameters and their significance to global net N<sub>2</sub>O production rates as well as to nitrification and denitrification, how current estimates and future projections of environmental conditions influence ocean production of N<sub>2</sub>O, and how the limitations of the model framework affect these results.

### 4.1 Significance of Uncertain Parameters

In order of most to least importance, the uncertain parameters and environmental conditions that have the greatest influence on global net N<sub>2</sub>O production rates are: O<sub>2</sub> data products,  $thr_{O_2}$  (the O<sub>2</sub> concentration that signifies the end of oxic remineralization and beginning of denitrification), the exponent  $c$  in  $\Omega$  (the constant that controls how strongly oxic remineralization rates decrease and denitrification rates increase with O<sub>2</sub> in suboxic waters),  $\alpha_{RLS}$  (the inverse remineralization length scale), spatial distribution of detritus flux (choice of Earth System Models used to generate EPC),  $K_{O_2,cons}$  (the O<sub>2</sub> concentration that signifies the start of N<sub>2</sub>O consumption),  $fNO_{3,rem}$  (the half-saturation threshold for denitrification/suboxic remineralization), and  $\gamma$  (the yield parameterization for N<sub>2</sub>O production by nitrification).

In general, O<sub>2</sub> has the greatest control on N<sub>2</sub>O production rates and so the input O<sub>2</sub> data product has substantial influence on model results, as do the parameters that control the proportions of oxic to suboxic remineralization ( $thr_{O_2}$  and  $c$ ) and the parameter that controls the proportion of N<sub>2</sub>O production by denitrification to consumption by denitrification ( $K_{O_2,cons}$ ).  $K_{O_2,cons}$  has a substantial influence on net N<sub>2</sub>O production, though its impact is relative to the strength of denitrification production and consumption as determined by  $thr_{O_2}$  and  $c$ . N<sub>2</sub>O yield ( $\gamma$ ) has strong control over N<sub>2</sub>O production by nitrification but does not have a very powerful impact on net N<sub>2</sub>O production, as nitrification contributes a relatively small amount of the total net N<sub>2</sub>O production. The accuracy of O<sub>2</sub> data products and the exact O<sub>2</sub> concentration of  $thr_{O_2}$  and  $K_{O_2,cons}$  are essential when parameterizing N<sub>2</sub>O production but are highly uncertain in past modelling and observational studies. In comparison, N<sub>2</sub>O yield during nitrification is generally well-understood although the new parameterization of  $\gamma$  is still relatively recent (Ji et al. 2018).

#### 4.1.1 Control by Oxygen

While the parameters  $thr_{O_2}$ ,  $c$ ,  $K_{O_2,cons}$ , and  $\gamma$  are both uncertain and highly influential to N<sub>2</sub>O production and consumption, the largest control on ocean N<sub>2</sub>O production is the accuracy of the O<sub>2</sub> data input to the model. To evaluate denitrification reactions that only occur in suboxic regions, it is essential that the gridded O<sub>2</sub> data is accurate in the 0-6  $\mu\text{mol}$  range. Interpolation of O<sub>2</sub> data products to a uniform 3D grid or averaging of monthly data to an annual mean can ‘smear out’ suboxic O<sub>2</sub> data points, leading to severe underrepresentation of denitrification processes taking place and, consequently, underestimation of N<sub>2</sub>O production and consumption by denitrification. As denitrification is responsible for a majority of net global N<sub>2</sub>O production in this model, the relative control by parameters  $thr_{O_2}$ ,  $c$ ,  $K_{O_2,cons}$ , and  $\gamma$  cannot be properly assessed without accurate suboxic O<sub>2</sub> data.

Averaging monthly O<sub>2</sub> data products from World Ocean Atlas 2018 to an annual mean leads to loss of 75-100% of grid cells with O<sub>2</sub> concentrations below 4 μmol-O<sub>2</sub> L<sup>-1</sup>. As this model has a  $thr_{O_2}$  of 6 μmol-O<sub>2</sub> L<sup>-1</sup> to signify the end of N<sub>2</sub>O production by denitrification and a  $K_{O_2,cons}$  of 0.3 μmol-O<sub>2</sub> L<sup>-1</sup> to control N<sub>2</sub>O consumption, using this annually-averaged O<sub>2</sub> data leads to a 65% decrease in the global net N<sub>2</sub>O production rate compared to using monthly O<sub>2</sub> data (note that monthly O<sub>2</sub> data is a relatively recent addition to the World Ocean Atlas). Newly developed O<sub>2</sub> data products (Kwiecewski and Babbin, 2021) have higher resolution due to using continuous depth profiles with higher resolution across depth layers as well as due to a greater amount of data points in total, which results in over ten times the fraction of suboxic data points as the World Ocean Atlas 2018. 11.6% of all data points lie in the 0-6 μmol-O<sub>2</sub> L<sup>-1</sup> region for the Kwiecewski and Babbin data as opposed to 0.50% for the World Ocean Atlas data, though this number may be biased high as Kwiecewski and Babbin's (2021) data is not interpolated to a uniform grid and is focused on ODZ regions in the Pacific. As such, O<sub>2</sub> data for Kwiecewski and Babbin (2021) and the World Ocean Atlas can not be directly compared. However, many ODZ regions in the World Ocean Atlas do not reach the 6 μmol-O<sub>2</sub> L<sup>-1</sup> threshold for denitrification at all, while it did in multiple locations in Kwiecewski and Babbin's (2021) data.

Furthermore, Kwiecewski and Babbin's (2021) O<sub>2</sub> data portrays the oxycline in ODZs as occurring at shallower depths than in the World Ocean Atlas for almost all locations. This has substantial influence on N<sub>2</sub>O production rates, as there is higher organic matter availability in shallower waters. Overlap of higher organic matter supply in locations with suboxic O<sub>2</sub> provides a greater amount of substrate for suboxic remineralization, and so increases N<sub>2</sub>O production and consumption by denitrification. In a location in the North Pacific ODZ (15°N, 110°W), O<sub>2</sub> concentrations reach as low as 2 μmol-O<sub>2</sub> L<sup>-1</sup> for the Kwiecewski and Babbin (2021) data set compared to 4 μmol-O<sub>2</sub> L<sup>-1</sup> for the World Ocean Atlas, and have an oxycline that begins at approximately 50 m as opposed to 150 m. These two factors lead to an increase in maximum net N<sub>2</sub>O production of nearly 50-fold, from 0.028 nmol-N<sub>2</sub>O L<sup>-1</sup> (World Ocean Atlas) to 1.25 nmol-N<sub>2</sub>O L<sup>-1</sup> (Kwiecewski and Babbin, 2021), and so have large repercussions for modelling ocean N<sub>2</sub>O production.

As far as O<sub>2</sub> control through parameter choices,  $thr_{O_2}$  is one of the most impactful terms for modelling N<sub>2</sub>O production through denitrification. This concentration is difficult to isolate due to the overlap of oxic remineralization and suboxic remineralization (denitrification) over a small range of suboxic O<sub>2</sub> concentrations. A difference of 1 μmol-O<sub>2</sub> L<sup>-1</sup> can determine the difference between oxic and suboxic processes, and so measuring  $thr_{O_2}$  would require extreme accuracy in sample measurement and analysis. The reaction rates of each of these processes can also vary widely due to influence by substrate availability and other environmental conditions, so while consumption of organic matter or electron acceptors (O<sub>2</sub> for oxic remineralization, NO<sub>3</sub><sup>-</sup> for suboxic remineralization) can be measured *in situ*, the relative magnitude of contribution by oxic versus suboxic remineralization is challenging. In other words, a decrease in organic matter over time can be directly measured but determining whether this organic matter is consumed by the oxic pathway or suboxic pathway is more complicated as it is not solely dependent on O<sub>2</sub>.

Isolating  $thr_{O_2}$  is also complicated by simplification of past model's parameterization of these individual reaction mechanisms. Often, elevated N<sub>2</sub>O production at ODZ oxyclines is represented by one term that signifies N<sub>2</sub>O production in suboxic O<sub>2</sub> by both nitrification and denitrification, and N<sub>2</sub>O consumption is represented simply as 'no production' after a certain low O<sub>2</sub> concentration is reached (Suntharalingam et al. 2000, Nevison et al. 2003, Bianchi et al.

2012). Because of this, the  $O_2$  threshold that partitions oxic and suboxic remineralization in many models disregards denitrification's ability to simultaneously produce and consume  $N_2O$  and conflates the  $O_2$  concentration for elevated  $N_2O$  yield with the  $O_2$  concentration for the start of denitrification  $N_2O$  production.

For example, strong accumulation of  $N_2O$  at higher  $O_2$  concentrations (such as  $20 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) has been measured in ODZ oxyclines that could indicate that the threshold for denitrification is higher than  $6 \mu\text{mol-O}_2 \text{ L}^{-1}$  (Farías et al. 2009, Sun et al. 2021), but it could also indicate elevated production by nitrification (Trimmer et al. 2016), or even the influence of other completely unrelated environmental conditions such as increased substrate supply or the effects of physical mixing at ODZ boundaries (Casciotti et al. 2018, Monreal et al. 2022). It is also uncertain whether elevated  $N_2O$  production is purely because of elevated  $N_2O$  production, or the absence of  $N_2O$  consumption.

Sun et al.'s (2021) model increased the  $O_2$  threshold for oxic versus suboxic remineralization to  $20 \mu\text{mol-O}_2 \text{ L}^{-1}$  from the  $1 \mu\text{mol-O}_2 \text{ L}^{-1}$  used in Babbin et al. (2015), and the resultant high global  $N_2O$  production rates caused them to similarly increase the  $K_{O_2,cons}$  from  $0.3 \mu\text{mol-O}_2 \text{ L}^{-1}$  to  $4.5 \mu\text{mol-O}_2 \text{ L}^{-1}$  in order to lower net  $N_2O$  production rates through increased  $N_2O$  consumption. If Babbin et al. (2015) are correct, then  $N_2O$  production has smaller denitrification source and sink terms than represented by Sun et al. (2021) and yet, both models produce similar global net  $N_2O$  production rates ( $3\text{-}5 \text{ Tg-N y}^{-1}$ ).

The model developed for this thesis uses a commonly accepted  $thr_{O_2}$  of  $6 \mu\text{mol-O}_2 \text{ L}^{-1}$  (e.g., Devol 2008) and has found that such a threshold leads to moderately high denitrification  $N_2O$  production rates, which are accompanied by moderate denitrification consumption rates. However, the model tests a  $thr_{O_2}$  range from  $1\text{-}20 \mu\text{mol-O}_2 \text{ L}^{-1}$ , resulting in net  $N_2O$  production rates from  $5.6 \text{ Tg-N y}^{-1}$  to  $57.9 \text{ Tg-N y}^{-1}$ . In this model, a  $thr_{O_2}$  of  $20 \mu\text{mol-O}_2 \text{ L}^{-1}$  results in denitrification production rates (without including  $N_2O$  consumption) as high as  $65.8 \text{ Tg-N y}^{-1}$ , compared to the  $19.2 \text{ Tg-N y}^{-1}$  produced when using a  $thr_{O_2}$  of  $6 \mu\text{mol-O}_2 \text{ L}^{-1}$ .

While past model estimates of pelagic denitrification (total denitrification, including  $\text{NO}_3^-$  reduction to  $\text{N}_2$ ) have reached much higher than  $65 \text{ Tg-N y}^{-1}$  (Gruber and Galloway 2008, Bianchi et al. 2012), estimates of  $N_2O$  production through denitrification reaching such high global totals are much less supported by past literature. Regardless, Sun et al.'s research posits an important question. Is there more denitrification – both incomplete ( $N_2O$  production) and complete ( $N_2O$  consumption) – occurring at higher  $O_2$  concentrations than expected? The results from this research indicate that this is possible, as the high variability of net  $N_2O$  production rates from the sensitivity experiments may indicate very high production and consumption rates.

To further investigate the proportion of denitrification production to consumption, and the net production by denitrification compared to production by nitrification, two other parameters –  $c$  and  $K_{O_2,cons}$  – must also be considered. While  $thr_{O_2}$  sets the upper limit for suboxic processes, the exponent  $c$  in  $\Omega$  controls how quickly the proportion of suboxic remineralization increases (with respect to oxic remineralization) as  $O_2$  decreases, and so influences net production by denitrification in combination with  $thr_{O_2}$ .  $C$  is a term introduced by this model parameterization rather than a physical quantity that can be measured like  $O_2$  concentration.

The value of  $c = 3$  was chosen according to how  $c$  affects the shape of the  $\Omega$  curve (Figure 49). Research by Devol (1978) and Dalsgaard et al. (2012) indicates that  $c$  should be greater than 1 – i.e., the curve should be 'convex' rather than 'concave' – as the fraction of oxic remineralization

decreases gradually in the upper range of suboxic concentrations (3-6  $\mu\text{mol-O}_2 \text{ L}^{-1}$ ) and rapidly in the lower range (0-3  $\mu\text{mol-O}_2 \text{ L}^{-1}$ ). Beyond this, there is not much literature that dictates the range of  $c$ . This model tests a range from 1.5 to 6, which generates substantially different global net  $\text{N}_2\text{O}$  production rates and denitrification  $\text{N}_2\text{O}$  production rates (Figure 50, 51). A lower  $c = 1.5$  increases global net  $\text{N}_2\text{O}$  production rates to 20.5  $\text{Tg-N y}^{-1}$  while a higher  $c = 6$  decreases rates to 6.4  $\text{Tg-N y}^{-1}$ , resulting in a range of approximately 70% (see Section 3.5.4, Figure 51). The base case scenario using  $c = 3$  generates global net  $\text{N}_2\text{O}$  production rates of 11.5  $\text{Tg-N y}^{-1}$ .

In order to narrow down the most likely value of  $c$  (or to create a similar parameterization that moderates control by  $\text{O}_2$ ), modelling can be a useful complement to laboratory and *in situ* research. Trying to observe the proportion of oxic to suboxic remineralization is difficult to accomplish in a controlled laboratory environment, and nearly impossible to measure in the actual ocean across a consistent and small range of  $\text{O}_2$  concentrations.

The magnitude of  $\text{N}_2\text{O}$  production by denitrification is controlled by both  $thr_{\text{O}_2}$  and  $c$ , but the ratio of production by denitrification to consumption by denitrification is controlled by  $K_{\text{O}_2, \text{cons}}$ . While  $thr_{\text{O}_2}$  is a strict  $\text{O}_2$  threshold for the upper limit of denitrification and is mediated by  $c$ ,  $K_{\text{O}_2, \text{cons}}$  is not a threshold and is instead mediated by an exponential parameterization (Equation 10, Figure 9).

$\text{N}_2\text{O}$  consumption, or complete denitrification through reduction of  $\text{N}_2\text{O}$  to  $\text{N}_2$ , is generally expected to occur at  $\text{O}_2$  concentrations below 1  $\mu\text{mol-O}_2 \text{ L}^{-1}$  and for this reason the base case scenario of  $K_{\text{O}_2, \text{cons}}$  is 0.3  $\mu\text{mol-O}_2 \text{ L}^{-1}$  but a range from 0.3-4.5  $\mu\text{mol-O}_2 \text{ L}^{-1}$  was tested. This variation in  $K_{\text{O}_2, \text{cons}}$  generates global  $\text{N}_2\text{O}$  consumption rates between 8.4 and 13.9  $\text{Tg-N y}^{-1}$ , with  $\text{N}_2\text{O}$  production rates by denitrification remaining the same at 19.2  $\text{Tg-N y}^{-1}$ . The result is that net  $\text{N}_2\text{O}$  production rates can change by approximately 2.1 times over the range of  $K_{\text{O}_2, \text{cons}}$  values tested (Figure 53).

The base case where  $K_{\text{O}_2, \text{cons}} = 0.3 \mu\text{mol-O}_2 \text{ L}^{-1}$  represents a scenario where denitrification consumption rates are slightly less than 50% of the denitrification production rate, while a higher  $K_{\text{O}_2, \text{cons}}$  would have consumption rates that are almost 75% of denitrification production rates. Essentially, if  $\text{N}_2\text{O}$  consumption occurs at higher  $\text{O}_2$  concentrations then the global net  $\text{N}_2\text{O}$  production by denitrification will be smaller in proportion to  $\text{N}_2\text{O}$  production by nitrification. If  $\text{N}_2\text{O}$  consumption only occurs at near-anoxic  $\text{O}_2$ , then the net  $\text{N}_2\text{O}$  production rates by denitrification will remain high even when  $\text{N}_2\text{O}$  consumption is simultaneously occurring.

Unfortunately, the relative magnitude of  $thr_{\text{O}_2}$  and  $K_{\text{O}_2, \text{cons}}$  is hard to determine from model results as three scenarios arise that are all plausible. Firstly,  $thr_{\text{O}_2}$  could be in the higher range of values tested with a relatively low  $K_{\text{O}_2, \text{cons}}$ , such as our base case scenario where  $thr_{\text{O}_2} = 6 \mu\text{mol-O}_2 \text{ L}^{-1}$  and  $K_{\text{O}_2, \text{cons}} = 0.3 \mu\text{mol-O}_2 \text{ L}^{-1}$  that generates high denitrification production rates and high denitrification consumption rates to result in moderate net denitrification production of  $\text{N}_2\text{O}$ . Secondly,  $thr_{\text{O}_2}$  could be lower (e.g., 3  $\mu\text{mol-O}_2 \text{ L}^{-1}$ ) with a low  $K_{\text{O}_2, \text{cons}}$  ( $K_{\text{O}_2, \text{cons}} = 0.3 \mu\text{mol-O}_2 \text{ L}^{-1}$ ), which would generate moderate-to-low net denitrification production. Thirdly,  $thr_{\text{O}_2}$  could be moderate with a high  $K_{\text{O}_2, \text{cons}}$  (such as both  $thr_{\text{O}_2}$  and  $K_{\text{O}_2, \text{cons}} = 3 \mu\text{mol-O}_2 \text{ L}^{-1}$ ), which would result in nearly equal denitrification production and consumption rates for very low net denitrification production of  $\text{N}_2\text{O}$ . Determining which scenario is most likely is related to the relative production of  $\text{N}_2\text{O}$  by net denitrification production and by nitrification production, which is also uncertain in past literature. In this model, however,  $\text{N}_2\text{O}$  production by nitrification is always low, even at the boundaries of ODZs, and so moderate-to-high net production by

denitrification is the most likely choice as it reflects observations of high N<sub>2</sub>O at ODZ boundaries.

The final O<sub>2</sub>-relevant parameter that exhibits a moderate influence on global N<sub>2</sub>O production rates is  $\gamma$  – yield of N<sub>2</sub>O from nitrification. The constants  $a$  and  $b$  in  $\gamma$  determine how much N<sub>2</sub>O is produced during nitrification. Therefore, the yield parameterization controls N<sub>2</sub>O production through nitrification (*Equation 6*, Figure 45) and the proportion of N<sub>2</sub>O produced by nitrification relative to denitrification. Varying parameterizations for  $\gamma$  generate a wide range of global nitrification N<sub>2</sub>O production rates between 0.37-1.41 Tg-N y<sup>-1</sup>. However, when this is considered in relation to global net N<sub>2</sub>O production rates, this amounts to a maximum of 8.4% of global net production. Therefore, the choice of parameterization for  $\gamma$  has a large effect on nitrification production of N<sub>2</sub>O but a modest effect on global net N<sub>2</sub>O production rate.

If the proportion of N<sub>2</sub>O produced by nitrification was much greater than in this model, as has occasionally been posited (Freing et al. 2012), then the N<sub>2</sub>O yield would have much greater importance. However, the relative amount of global N<sub>2</sub>O production from nitrification and denitrification is still a question without a definitive answer. The results from this model suggest that denitrification production of N<sub>2</sub>O is the dominant pathway in the global ocean and that N<sub>2</sub>O production rates by denitrification have been underestimated in many past studies, but it is still uncertain exactly how much N<sub>2</sub>O is produced by denitrification and by nitrification.

Regardless of the magnitude of N<sub>2</sub>O production by nitrification in the global ocean,  $\gamma$  and N<sub>2</sub>O production by nitrification need more scrutiny, especially in low O<sub>2</sub> regions and with the perspective of the full system of N<sub>2</sub>O production and consumption mechanisms. While yield is increased at low O<sub>2</sub>, nitrification rates are decreased at low O<sub>2</sub>, and the cumulative effect of this on a global scale is uncertain. Specific instances of elevated N<sub>2</sub>O production by nitrification at low O<sub>2</sub> (Goreau et al. 1980, Nevison et al. 2003) have been observed but often lack the necessary context. In other words, is observed elevated N<sub>2</sub>O production by nitrification at a certain location purely due to an O<sub>2</sub> effect on yield and reaction rates, or is it due to other influences like organic matter supply?

If one assumes that nitrification is the dominant N<sub>2</sub>O production pathway in the ocean, then the sensitivity of global net N<sub>2</sub>O production to  $\gamma$  is of paramount importance. However, the results from this model have shown no scenario where global nitrification production of N<sub>2</sub>O is higher than denitrification production of N<sub>2</sub>O. Even with the N<sub>2</sub>O yield parameterization that produces the highest nitrification N<sub>2</sub>O production rates of 1.4 Tg-N y<sup>-1</sup> (Figure 44), nitrification N<sub>2</sub>O production only contributes up to 11.6% of global net N<sub>2</sub>O production (Figure 45). Furthermore, scenarios that lower the net global denitrification production rate never approach the 1.5 Tg-N y<sup>-1</sup> of nitrification N<sub>2</sub>O production – the lowest net denitrification production rate is 4.8 Tg-N y<sup>-1</sup> (Figure 48).

It should be noted that this research does not include contributions of nitrification within the euphotic zone. As this model does not include reaction in the euphotic zone or any depths above 100 m, it is likely that nitrification N<sub>2</sub>O production rates are higher than estimated here. Nevertheless, this was considered an acceptable concession as N<sub>2</sub>O production in the euphotic zone is expected to be low (Yool et al. 2007, Freing et al. 2012, Grundle 2012, Zamora and Oschlies 2014). Euphotic zone nitrification therefore is not expected to qualitatively change the proportion of nitrification N<sub>2</sub>O production in terms of global net N<sub>2</sub>O production.

#### 4.1.2 Control by Organic Matter Supply

While  $O_2$  controls the proportion of oxic versus suboxic processes and the rates of  $N_2O$  production by nitrification and denitrification, detrital organic matter serves as the initial ‘fuel’ for the system of reactions. The model input of detritus comes from particulate matter exported from the euphotic zone, and the amount of available organic matter dictates how much of all the reactions in the system (remineralization, nitrification, denitrification) occur. If there is a substantial amount of detritus exported from the euphotic zone, there will be ample substrate to be remineralized to  $NH_4^+$  and consequently converted to  $N_2O$  and  $NO_3^-$  through nitrification (oxic pathway) or aiding in  $NO_3^-$  remineralization to  $N_2O$  (suboxic pathway). Since detritus is consumed in both oxic and suboxic pathways, it can affect  $N_2O$  production through nitrification and denitrification directly and indirectly. High availability of detritus generally implies higher  $N_2O$  production rates, although the exact magnitudes of the  $N_2O$  production and consumption rates are influenced by other environmental conditions such as  $O_2$ .

The influence of organic matter supply and remineralization was tested using EPC (export production of carbon) data generated by five different Earth System models – CanESM5, CanESM5-CaNOE, CNRM-ESM2-1, GFDL-ESM4, and UKESM1-0-LL – since observation-based estimates of EPC are highly uncertain and/or of low spatial resolution (e.g., Schlitzer 2000). The spatial variation of EPC can lead to substantial differences in global net  $N_2O$  production rates. This affects denitrification production and consumption rates in particular as the location of high organic matter supply in relation to suboxic  $O_2$  concentrations is of particular importance.

Among the EPC data from the five Earth System models, there is a range of almost twofold in global net  $N_2O$  production rates, with GFDL-ESM4 providing the lowest ( $9.6 \text{ Tg-N y}^{-1}$ ) and UKESM1-0-LL the highest ( $17.3 \text{ Tg-N y}^{-1}$ ) global net  $N_2O$  production. This is reasonable given the variability in spatial distribution of EPC (Figure 31). In general, CanESM5, CanESM5-CaNOE, and UKESM1-0-LL show more organic matter availability in ODZ locations than CNRM-ESM2-1 and GFDL-ESM4. However, the interactions between high organic matter supply, suboxic  $O_2$  that promotes  $N_2O$  production through denitrification, and the near-anoxic  $O_2$  that allows  $N_2O$  consumption by denitrification results in UKESM1-0-LL having the highest global net  $N_2O$  production rate, with CNRM-ESM2-1 the second highest (Figure 32).

The attenuation of detritus flux with depth was parameterized in this model as a simple exponential decay. The inverse remineralization length scale,  $\alpha_{RLS}$ , determines how quickly detritus flux decreases with depth (see *Equation 12*; Figure 33). The steepness of this curve determines availability of organic matter in relation to regions of suboxic  $O_2$  concentrations, especially when considering that the upper oxycline of ODZs (where  $N_2O$  production rates are highest) frequently occurs at 100-300 m depth and that ODZs can persist to much greater depths ( $\geq 1000 \text{ m}$ ).

Testing a range of  $\alpha_{RLS}$  between  $0.001 - 0.020 \text{ m}^{-1}$  generated a substantial difference in global net  $N_2O$  production rates, and while it did not affect rates quite as strongly as spatial variation in the EPC, the model is still quite sensitive to  $\alpha_{RLS}$ . In general, increasing  $\alpha_{RLS}$  will decrease net  $N_2O$  production rates due to a strong effect on denitrification. This is once again related to not only how much detritus is available, but the location of where it is available – a higher  $\alpha_{RLS}$  provides less organic matter to the regions where denitrification occurs. An exception to this is the lowest tested  $\alpha_{RLS}$  of  $0.001 \text{ m}^{-1}$ . (Figure 33, bottom). In this case, input of organic matter is low at all depths. This includes the region above ODZs near the oxycline that normally generate high  $N_2O$

production rates, as much of the detritus is instead transported to greater depths below the ODZ (Figure 33).

Notably, this model does not directly include the full effect of temperature and  $O_2$  on remineralization rates. The consumption of detritus in the model's  $d[D]/dt$  process equation is influenced by temperature using the Arrhenius equation (Equation 1, 2), but  $O_2$  controls the partitioning of suboxic and oxic remineralization processes without influencing the rate magnitude. Since this model uses a constant remineralization length scale ( $\alpha_{RLS}$ ) for the flux of EPC exported from the euphotic zone, the effects of  $O_2$  and temperature variations on the detrital input to the model are considered negligible. In other words, the change in detrital organic matter supply ([D]) with depth is assumed to be the same for all locations, with no difference between ODZ regions or other, better oxygenated regions, which is not true in the real world. If the effects of  $O_2$  and temperature in ODZs were considered in terms of the supply of organic matter exported from the euphotic zone, it is most likely that the model estimates of denitrification would be lower as there would be less overall organic matter supplied in ODZ regions (Devol and Hartnett 2001, Cram et al. 2021). Although  $N_2O$  production by denitrification is high in this model compared to past model studies, overall denitrification as it pertains to the nitrogen budget is comparatively low (discussed further in Section 4.2).

While denitrification rates tend to decrease with higher  $\alpha_{RLS}$ , nitrification  $N_2O$  production rates increase with higher  $\alpha_{RLS}$ . This is because the location-specific interaction of detritus availability and  $O_2$  concentration is much less relevant for nitrification than for denitrification. Nitrification occurs throughout the oxygenated ocean, so changes in the total amount of detritus input into the model from varying  $\alpha_{RLS}$  will affect nitrification  $N_2O$  production rates more than localized detritus availability in suboxic regions.

The effect of varying  $\alpha_{RLS}$  is slightly higher for nitrification than for denitrification: denitrification production rates vary by 36%, while nitrification rates vary by 39% for a total maximum effect on global net  $N_2O$  production rates of 35% as rates vary between 7.5-11.5 Tg-N  $y^{-1}$ . The global proportion of  $N_2O$  produced by nitrification compared to  $N_2O$  produced by denitrification remains small.

The combined influence of  $\alpha_{RLS}$  and the spatial pattern of EPC at 100 m on detritus input into the model is large, and organic matter supply affects  $N_2O$  production rates not only by magnitude but by its location in relation to suboxic regions that permit denitrification and associated  $N_2O$  production.

#### 4.1.3 Control by Other Parameters

As discussed earlier, denitrification requires both organic matter and low  $O_2$  concentration; however, it also requires  $NO_3^-$ . To test whether  $NO_3^-$  limitation of suboxic remineralization can affect global  $N_2O$  production rate, the half-saturation constant  $K_{NO_3,rem}$  was varied between 0.1 – 30  $\mu\text{mol-NO}_3^- \text{L}^{-1}$  (see Figure 42, 43). Increasing  $K_{NO_3,rem}$  will decrease  $N_2O$  production by denitrification as it raises the requirement for  $NO_3^-$  availability. Global net  $N_2O$  production rates ranged from 7.6-13.0 Tg-N  $y^{-1}$  from altering  $K_{NO_3,rem}$  alone for a maximum difference of 42% - a substantial difference that is on a scale comparable to the influence of  $O_2$  and organic matter availability.

There is little literature that addresses the degree to which low  $NO_3^-$  concentrations affect denitrification rates through a parameter such as  $K_{NO_3,rem}$ . This is in part because there are few studies that separate the denitrification reaction into two steps – reduction of  $NO_3^-$  to  $N_2O$  and

subsequent reduction of  $\text{N}_2\text{O}$  to  $\text{N}_2$  – and it is difficult to accurately measure rate kinetics *in situ* across the multiple intermediates present in this multi-step reaction. Experimental studies indicate that enzymes used by each step of denitrification exhibit different reaction kinetics (see Figure 1, top panel) and are activated at different  $\text{O}_2$  concentrations (Casciotti et al. 2018, Rees et al. 2021, Sun et al. 2021). Conflating the behaviour of these various reaction mechanisms may in part be responsible for the uncertainty of parameters and parameterizations for denitrification production and consumption of  $\text{N}_2\text{O}$ . For example, if denitrification is considered solely as reduction of  $\text{NO}_3^-$ , it would be reasonable to investigate reaction kinetics by measuring  $\text{NO}_3^-$  loss in suboxic waters. Unfortunately, doing so would ignore different reaction behaviours for reduction of  $\text{NO}_3^-$ ,  $\text{NO}_2^-$ ,  $\text{NO}$ , and  $\text{N}_2\text{O}$  to  $\text{N}_2$ , all of which use different enzymes, are activated at different  $\text{O}_2$  concentrations, and can vary widely across microbial communities. Understanding how strongly these reaction steps differ is difficult to measure *in situ* and in laboratories due to the fast cycling rates of these reactions, but will be imperative to understanding the difference between production of  $\text{N}_2\text{O}$  (reduction of  $\text{NO}_3^-$  through  $\text{NO}_2^-$  and  $\text{NO}$  to  $\text{N}_2\text{O}$ ) and consumption of  $\text{N}_2\text{O}$  (reduction of  $\text{N}_2\text{O}$ ). Lacking more information, the base case scenario of  $K_{\text{NO}_3, \text{remin}} = 5 \mu\text{mol-NO}_3^- \text{L}^{-1}$  was chosen (see Section 2.1.1., Figure 6 and Section 3.5.1, Figure 42). Model sensitivity is low when comparing  $K_{\text{NO}_3, \text{remin}}$  values between 1-5  $\mu\text{mol-NO}_3^- \text{L}^{-1}$ , as  $\text{NO}_3^-$  concentrations from the WOA are almost always much higher than 5  $\mu\text{mol-NO}_3^- \text{L}^{-1}$ .

It is important to note that  $f_{\text{NO}_3, \text{remin}}$  also acts as a necessary ‘fail-safe’ for the model; without it, suboxic remineralization is only controlled by  $\text{O}_2$ . Exclusion of the  $f_{\text{NO}_3, \text{remin}}$  term can lead to scenarios with high suboxic remineralization rates that consume  $\text{NO}_3^-$  strongly enough for  $\text{NO}_3^-$  to become negative in the model. While  $\text{NO}_3^-$  is typically not a limiting reactant – there are no suboxic data points in World Ocean Atlas data where  $\text{NO}_3^- < 10 \mu\text{mol-NO}_3^- \text{L}^{-1}$  except in the Black Sea – extremely low  $\text{NO}_3^-$  concentrations do appear in ESM simulations.

The  $\text{O}_2$  half-saturation constant for nitrification  $K_{\text{O}_2, \text{AmOx}}$  did not show strong influence on nitrification  $\text{N}_2\text{O}$  production rates or global net  $\text{N}_2\text{O}$  production rates. The influence of  $K_{\text{O}_2, \text{AmOx}}$  on global  $\text{N}_2\text{O}$  production rates is minimal except at very high half-saturation constants (such as  $K_{\text{O}_2, \text{AmOx}} = 30 \mu\text{mol-O}_2 \text{L}^{-1}$ ) that severely restrict nitrification production of  $\text{N}_2\text{O}$ . The primary purpose of  $f_{\text{O}_2, \text{AmOx}}$  is to inhibit nitrification rates at very low  $\text{O}_2$  concentrations, but the nitrification production of  $\text{N}_2\text{O}$  by  $\text{O}_2$  is more influenced by the yield parameterization than by  $f_{\text{O}_2, \text{AmOx}}$ . While  $f_{\text{O}_2, \text{AmOx}}$  decreases the rate of nitrification at very low  $\text{O}_2$ ,  $\gamma$  controls the amount of  $\text{N}_2\text{O}$  produced by nitrification and increases at low  $\text{O}_2$ . Both terms are necessary to properly represent  $\text{N}_2\text{O}$  production rates by nitrification, but the sensitivity of global  $\text{N}_2\text{O}$  production to the yield is much greater (Figures 41, 45). Given a lack of literature data indicating otherwise, the base case scenario maintains a  $K_{\text{O}_2, \text{AmOx}}$  of 5  $\mu\text{mol-O}_2 \text{L}^{-1}$ .

## 4.2 Model Evaluation

The steady state framework that serves as the basis of this model provides an in depth look into the individual mechanisms of nitrification and denitrification by maintaining simplicity and allowing for control of environmental conditions, substrate input, and reaction and dilution rates, within the framework of the global 3D distribution of oxygen, nitrate and other environmental conditions. However, this simple framework also has drawbacks. In this section, the validity of this model framework will be assessed.

Assuming steady state conditions permits a direct relationship between the chemostat’s dilution rate and the reaction rate constants. As *in situ* nitrification and denitrification reaction rates are

extremely variable and the controls on the reaction rates are poorly understood, finding observation-based rate constants is challenging. The magnitude of the reaction rate constants used in the chemostat is determined by their relationship to the dilution rate rather than for their relationship to actual process rates.

While the simplicity of the model is its strength as it allows for better investigation of the individual reaction mechanisms in a controlled environment, there are a few terms that have been excluded due to the model scope and time constraints. Most significantly, the absence of transport mechanisms like advection and mixing may impact N<sub>2</sub>O production and consumption rates, especially in the regions at the boundaries of ODZs. These physical mechanisms can affect the distribution of N<sub>2</sub>O in and around ODZs, whether through the transport of N<sub>2</sub>O itself, or the transport of O<sub>2</sub> and reaction substrates that have a strong control on N<sub>2</sub>O production and consumption rates. For example, N<sub>2</sub>O transported away from strong suboxic zones with high denitrification production and consumption rates could ‘escape’ consumption by mixing with more oxygenated waters. This would increase net N<sub>2</sub>O production rates as well as increase N<sub>2</sub>O concentrations at the oxic boundaries of ODZs that might otherwise be attributed to N<sub>2</sub>O produced by nitrification. Incursions of oxygenated water into the ODZs could have effects on all three N<sub>2</sub>O production and consumption mechanisms; nitrification N<sub>2</sub>O yield would decrease even as nitrification rates increase, denitrification production could become elevated in relation to denitrification consumption, or both denitrification production and consumption could be inhibited.

#### 4.2.1 Reaction Rates and Rate Constants

This research focuses on analyzing N<sub>2</sub>O reaction rates rather than resulting N<sub>2</sub>O concentrations, as N<sub>2</sub>O concentrations in the chemostat effluent can not meaningfully be compared with observed concentrations. N<sub>2</sub>O can remain in the ocean for very long timescales, and N<sub>2</sub>O concentrations can accumulate substantially over time, especially in ODZ regions that are characterized by slow circulation of water masses. This model doesn’t account for physical and biological processes over long timescales or the age of water masses and so can not reliably represent N<sub>2</sub>O concentrations in real world conditions. As N<sub>2</sub>O reaction rates are primarily influenced by the immediate conditions of the surrounding environment, they serve as a more dependable method of analysis. However, reaction rates are dependent on substrate concentrations – N<sub>2</sub>O consumption rates, for example, are strongly influenced by the high N<sub>2</sub>O concentrations produced by denitrification N<sub>2</sub>O production – and so the influence of physical mechanisms that affect concentrations should not be ignored in future studies. While ODZ regions are characterized by weak circulation and slow movement of water masses, mechanisms such as eddy mixing at ODZ boundaries could have a substantial influence on N<sub>2</sub>O production rates (Grundle et al. 2017, Monreal et al. 2022) and so would affect model analysis of the proportion of N<sub>2</sub>O produced and consumed by denitrification and the proportion of N<sub>2</sub>O produced by nitrification compared to denitrification.

Using the steady state parameterization, the remineralization rate constant ( $k_{remin}$ ) is set to be equal to the dilution rate ( $DR = 0.25 \text{ d}^{-1}$ ) so that the rate of remineralization of detritus can be obtained from the attenuation of EPC flux from the euphotic zone.

*Equation 13* helps to explain this and so is reiterated here:

$$\frac{d[X]}{dt} = Source_X - Sink_X + DR([X]_{in} - [X]) = 0$$

At steady state,  $d[X]/dt = 0$ . This means that for detritus ( $[D]$ ), the rate of remineralization has to equal  $DR([D]_{in}-[D])$ .  $[D]$  does not equal exactly  $0.5[D]_{in}$ , but the selected rate for  $DR$  and  $k_{remin}$  in combination with the EPC normalization to  $20 \text{ Pg-C y}^{-1}$  means it is quite close. This allows the chemostat to generate a scenario where approximately half of the total EPC input is remineralized ( $8.52 \text{ Pg-C y}^{-1}$ ), which reflects literature estimates of approximately  $9 \text{ Pg-C y}^{-1}$  of export from the euphotic zone. Remineralization of this quantity of EPC consequently leads to a global nitrification rate (not nitrification production of  $\text{N}_2\text{O}$ ) of approximately  $189 \text{ Tg-N y}^{-1}$ .

As this is one of the few hard constraints to the model,  $k_{remin}$  and the dilution rate can not be arbitrarily adjusted without also ensuring that the changes result in a net of  $9 \text{ Pg-C y}^{-1}$ . The rate constants for nitrification ( $k_{AmOx}$ ) and  $\text{N}_2\text{O}$  consumption ( $k_{cons}$ ) are chosen to be high in relation to the  $DR$  and  $k_{remin}$  to simulate high reaction rates where most of the substrates for the reactions ( $\text{NH}_4^+$  for  $k_{AmOx}$  and  $\text{N}_2\text{O}$  for  $k_{cons}$ ) are consumed and little is left over in the chemostat effluent.

In the case of nitrification, this seems reasonable as very little  $\text{NH}_4^+$  remains available in the ocean for a substantial amount of time and so  $\text{NH}_4^+$  concentrations tend to be low. The rate constant for nitrification is constrained by  $\text{NH}_4^+$  concentrations – if  $k_{AmOx}$  was ten times smaller than  $k_{remin}$ , for example, then the steady state concentration of  $\text{NH}_4^+$  would be higher than what is observed *in situ* (typically  $< 0.1 \mu\text{mol-NH}_4^+ \text{ L}^{-1}$ ). A high rate constant for  $k_{AmOx}$  means that all of the  $\text{NH}_4^+$  is ultimately oxidized to  $\text{NO}_3^-$ , which is true in most ocean waters below the euphotic zone, as there are not many competing processes that consume the  $\text{NH}_4^+$  before it is oxidized. Within reasonable limits, this means that the exact rate at which nitrification occurs is unimportant in the steady state framework of the chemostat as long as it is high enough in relation to the remineralization rate to consume most of the  $\text{NH}_4^+$ . If there is leftover  $\text{NH}_4^+$  in the chemostat effluent, the model will underestimate  $\text{N}_2\text{O}$  production by nitrification (Figure 63).

**Figure 63:** Global N<sub>2</sub>O production and consumption rates with varying  $k_{AmOx}$ . Top panel depicts all production and consumption processes, bottom panel is a larger depiction of the nitrification production rates.

In Figure 63,  $k_{AmOx}$  was varied between 0.1-1.1 d<sup>-1</sup>, showing strong control on the nitrification N<sub>2</sub>O production rates which range from 0.27-0.80 Tg-N y<sup>-1</sup>. However, the validity of the lower rate constants is dubious for the reasons stated above – they do not consume all of the available NH<sub>4</sub><sup>+</sup>, and so underestimate N<sub>2</sub>O production by nitrification in comparison to the base case scenario ( $k_{AmOx} = 0.8$  d<sup>-1</sup>). As the rate constants are directly constrained by the model setup the

rate constant  $k_{AmOx}$  is set to create realistic rates of  $N_2O$  production under the somewhat artificial conditions of the chemostat and should not be assumed to represent real world values.

For  $N_2O$  consumption during denitrification, there is little available data from which to determine whether most of the  $N_2O$  available in ODZs is rapidly consumed or slowly consumed.  $N_2O$  that is produced in ODZs has been observed at locations far from their origin (e.g., Popp et al. 2002), and this export of  $N_2O$  from ODZs suggests that contemporaneous  $N_2O$  consumption does not remove all of the  $N_2O$  produced by denitrification in suboxic waters.

For the purposes of this model,  $k_{cons}$  was set to be as high as  $k_{AmOx}$  ( $0.8\text{ d}^{-1}$ ). The results demonstrate that even with a large  $k_{cons}$  (in viable conditions for  $N_2O$  consumption),  $N_2O$  production by denitrification remains higher than  $N_2O$  consumption by denitrification (Figure 64). The effect of the steady-state framework on the fraction of  $N_2O$  consumed is discussed further below.

**Figure 64:** Global  $N_2O$  production and consumption rates with varying  $k_{cons}$

Changes in the consumption rate by altering  $k_{cons}$  are substantial and have a large degree of control over net  $N_2O$  production rates (Figure 64). As  $N_2O$  production and consumption occurs rapidly and is controlled by a small range of  $O_2$  – it is not known whether most of the  $N_2O$  should be consumed in each daily time step or if much of the  $N_2O$  produced should be left over in the effluent.

Even when  $k_{cons}$  is at its highest ( $1.1\text{ d}^{-1}$ ) and the global consumption rate is increased to  $-9.1\text{ Tg-N y}^{-1}$ ,  $N_2O$  production (especially by denitrification) still greatly exceeds consumption. This implies that there is a surplus of  $N_2O$  generated, and that denitrification production in ODZs exports more  $N_2O$  outside of its suboxic waters than is consumed within the ODZ boundaries. The experiments with  $K_{O_2,cons}$  – the  $O_2$  concentration that controls when  $N_2O$  consumption

begins – also support this, as even increasing  $K_{O_2,cons}$  to a high  $O_2$  concentration results in denitrification production that far exceeds consumption.

It should be noted, however, that the nature of the reaction pathway for  $N_2O$  consumption requires production of  $N_2O$  in order to provide a substrate for consumption, and therefore  $N_2O$  production by denitrification must be higher than consumption by denitrification – both in this model and in real world conditions. One exception to this would be if there was very high  $N_2O$  production by nitrification that provides ample  $N_2O$  as a substrate for high  $N_2O$  consumption rates, but it is very unlikely that nitrification  $N_2O$  production is this strong in the near-anoxic waters that are capable of  $N_2O$  consumption by denitrification. Another such exception would be mixing of waters with moderately-high suboxic concentrations ( $\sim 3 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) - that produce high  $N_2O$  concentrations due to denitrification production of  $N_2O$  - with near-anoxic waters ( $< 1 \mu\text{mol-O}_2 \text{ L}^{-1}$ ) where  $N_2O$  consumption occurs. In both scenarios,  $N_2O$  consumption could exceed production by denitrification as a result of high  $N_2O$  concentrations that aren't directly related to denitrification  $N_2O$  production at that location, in a location with low enough  $O_2$  to support  $N_2O$  consumption.

#### 4.2.2 $N_2O$ Residence Time

To further test the above hypothesis, the  $N_2O$  residence time with respect to the  $N_2O$  consumption rate is evaluated in locations with varying  $O_2$  concentrations in order to see how much and how quickly  $N_2O$  is consumed according to  $O_2$ . Residence times were calculated for all 3D global locations as well as for a specific location in the North Pacific ODZ where  $O_2$  is known to be low enough for  $N_2O$  consumption to take place. Additionally, an experiment was conducted to evaluate  $N_2O$  concentrations across steadily increasing  $O_2$  concentrations as they are affected by the  $N_2O$  consumption rate alone. The intent of this experiment is to mimic the transport of a water parcel containing  $N_2O$  away from the ODZ and into more oxygenated waters.

Residence time is calculated by taking the  $N_2O$  concentration divided by the  $N_2O$  consumption rate at that location.

$$N_2O \text{ Residence Time} = \frac{[N_2O]}{N_2O \text{ Consumption Rate}}$$

*Equation 15*

The residence time for all global locations with relatively low  $O_2$  concentrations (0-30  $\mu\text{mol-O}_2 \text{ L}^{-1}$ , using input  $O_2$  from Bianchi-corrected World Ocean Atlas data rather than model-generated steady state  $O_2$  concentrations) is shown in Figure 65.

**Figure 65:** N<sub>2</sub>O residence times with respect to N<sub>2</sub>O consumption across multiple global locations.

Although Figure 65 mainly depicts residence times in the lower O<sub>2</sub> range, the model also calculates extremely high residence times at higher O<sub>2</sub> concentrations. The exponential parameterization for N<sub>2</sub>O consumption is such that N<sub>2</sub>O consumption occurs even in oxic waters, but at such low rates that they can be considered negligible. Such low consumption rates would lead to extremely high residence times for N<sub>2</sub>O but are not relevant to the relationship between O<sub>2</sub> and N<sub>2</sub>O consumption discussed here, nor to global net N<sub>2</sub>O production rates. The residence times for N<sub>2</sub>O in relation to the N<sub>2</sub>O consumption rate as depicted by Figure 65 can help describe how N<sub>2</sub>O consumption rates and N<sub>2</sub>O concentrations relate at various O<sub>2</sub> concentrations, though the relationship is not always straightforward.

In the range of 0.3-3 µmol-O<sub>2</sub> L<sup>-1</sup> where denitrification N<sub>2</sub>O production is high and N<sub>2</sub>O consumption is low, residence times are high. In the 3-10 µmol-O<sub>2</sub> L<sup>-1</sup> range where denitrification production of N<sub>2</sub>O is moderate but N<sub>2</sub>O consumption is near zero, residence times are also high. Comparatively, in the small range between 0-0.3 µmol-O<sub>2</sub> L<sup>-1</sup> where N<sub>2</sub>O consumption is high, residence times are low.

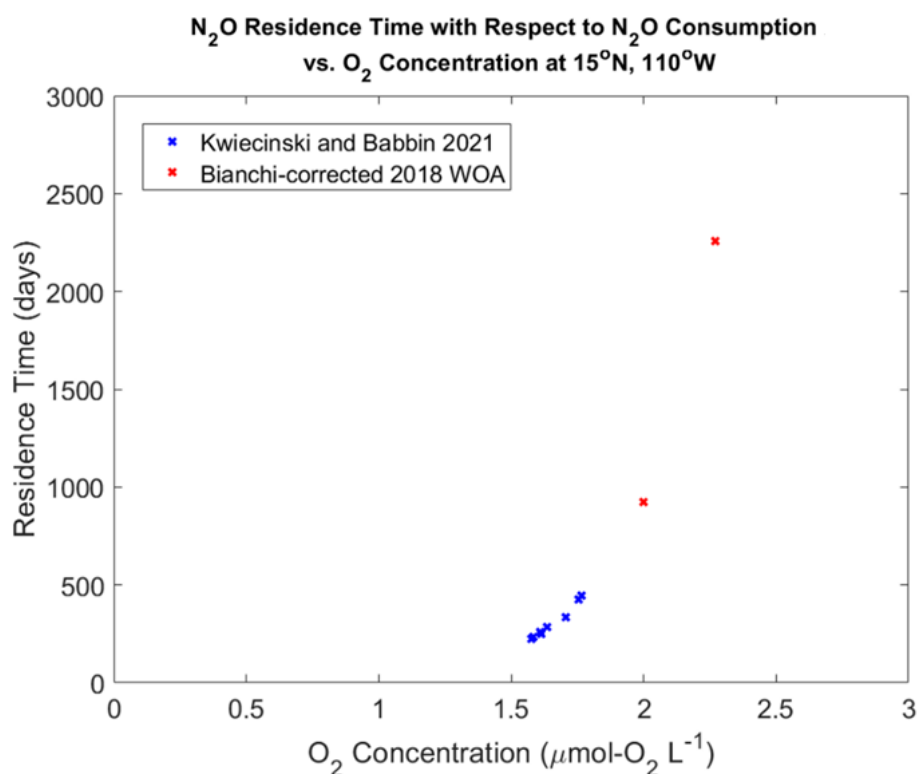

To take a closer look at this interaction a location-specific investigation was conducted on residence times in the North Pacific ODZ (Figure 66), which includes  $O_2$  and  $N_2O$  concentrations alongside  $N_2O$  production and consumption rates by denitrification for perspective.

**Figure 66:**  $O_2$  concentrations,  $N_2O$  concentrations,  $N_2O$  production and consumption rates by denitrification, and  $N_2O$  residence times with respect to  $N_2O$  consumption at a location in the North Pacific ODZ ( $15^\circ N$ ,  $110^\circ W$ ) for three  $O_2$  data sets: Kwiecinski & Babbini 2021 (blue), 2018 World Ocean Atlas (WOA) (black), and Bianchi-corrected WOA2018 (red).

As the 2018 WOA O<sub>2</sub> data products (black) do not reach concentrations low enough for substantial N<sub>2</sub>O consumption at this location, only the Bianchi-corrected 2018 WOA data products (red) and Kwiecinski and Babbin 2021 data products (blue) residence times are calculated. The residence times for the Bianchi-corrected 2018 WOA data are larger than for the Kwiecinski and Babbin 2021 data because the N<sub>2</sub>O consumption rates are lower. Residence time is shown for the Bianchi-corrected data for only two depths because these are the only ones with substantial consumption rates.

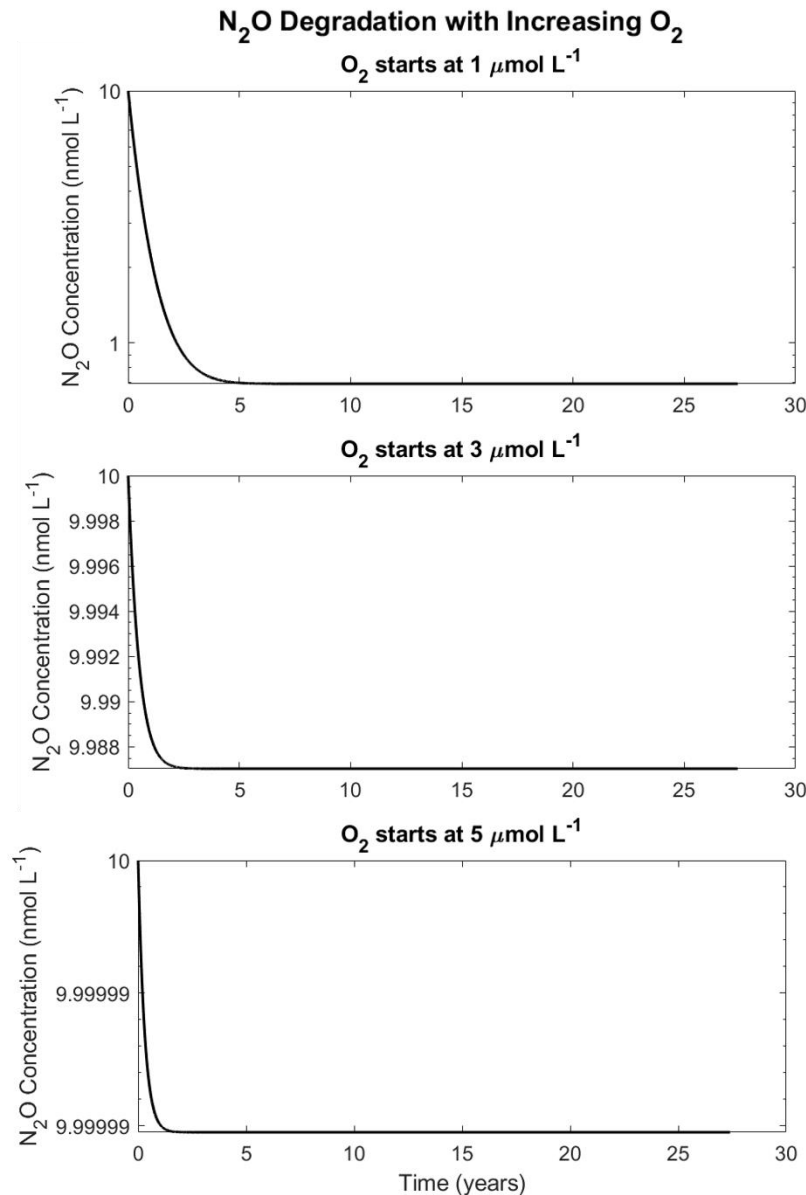

The residence times calculated for the Kwiecinski and Babbin data and the Bianchi-corrected 2018 WOA data at this location are plotted against O<sub>2</sub> concentration in Figure 67. The smaller residence times for the Kwiecinski and Babbin O<sub>2</sub> data occur at lower O<sub>2</sub> concentrations because lower O<sub>2</sub> allows for greater N<sub>2</sub>O consumption rates. The change in N<sub>2</sub>O consumption rates is more important than the change in N<sub>2</sub>O concentrations because N<sub>2</sub>O production by denitrification remains high.

**Figure 67:** N<sub>2</sub>O residence time with respect to N<sub>2</sub>O consumption vs. input O<sub>2</sub> concentration at a location in the North Pacific ODZ (15°N, 110°W) for two O<sub>2</sub> data sets: Kwiecinski and Babbin 2021 (blue) and Bianchi-corrected 2018 World Ocean Atlas (WOA) (red).

In Figure 67, the residence times of N<sub>2</sub>O with respect to the N<sub>2</sub>O consumption rates decrease at lower O<sub>2</sub> concentrations and increase at higher O<sub>2</sub> concentrations. This is an expected conclusion when considering the shape of the curve for the N<sub>2</sub>O consumption rate parameterization (*Equation 10*). While N<sub>2</sub>O consumption rates can be large in near-anoxic waters, substantial consumption of N<sub>2</sub>O is almost exclusively limited to ODZs. This means that any export of N<sub>2</sub>O from ODZs will potentially remain in circulation for centuries until it is either released into the atmosphere or brought back to regions with extremely low O<sub>2</sub>.

We can further investigate how  $\text{N}_2\text{O}$  is consumed by plotting  $\text{N}_2\text{O}$  consumption term over time (Figure 68). Since  $\text{N}_2\text{O}$  consumption rates change with  $\text{O}_2$  concentrations, three ‘starting points’ of  $[\text{O}_2]$  are depicted: 1, 3, and 5  $\mu\text{mol-O}_2 \text{ L}^{-1}$ . All three experiments increase  $\text{O}_2$  by 0.05% per day as a conservative estimate of how a water parcel might experience elevated  $\text{O}_2$  by mixing with outside, more oxygenated waters.  $\text{O}_2$  that starts at 1  $\mu\text{mol-O}_2 \text{ L}^{-1}$  will increase to 2.5  $\mu\text{mol-O}_2 \text{ L}^{-1}$  in 5 years and 6.2  $\mu\text{mol-O}_2 \text{ L}^{-1}$  in 10 years,  $\text{O}_2$  that starts at 3  $\mu\text{mol-O}_2 \text{ L}^{-1}$  will increase to 7.5  $\mu\text{mol-O}_2 \text{ L}^{-1}$  in 5 years and 18.6  $\mu\text{mol-O}_2 \text{ L}^{-1}$  in 10 years, and  $\text{O}_2$  that starts at 5  $\mu\text{mol-O}_2 \text{ L}^{-1}$  will increase to 12.4  $\mu\text{mol-O}_2 \text{ L}^{-1}$  in 5 years and 31.0  $\mu\text{mol-O}_2 \text{ L}^{-1}$  in 10 years.

**Figure 68:**  $\text{N}_2\text{O}$  degradation through denitrification  $\text{N}_2\text{O}$  consumption over time with a range of different starting  $\text{O}_2$  concentrations and a rate of increase of 0.05%  $\text{d}^{-1}$ .

Using the same starting concentration of  $\text{N}_2\text{O}$  but different starting concentrations of  $\text{O}_2$  generates different asymptotic concentrations of  $\text{N}_2\text{O}$ . When  $\text{O}_2$  is 3  $\mu\text{mol-O}_2 \text{ L}^{-1}$  or higher, the degradation of  $\text{N}_2\text{O}$  over time with increasing  $\text{O}_2$  is extremely low, only decreasing  $\text{N}_2\text{O}$

concentrations by less than 0.2% (Figure 68, middle and bottom). However, when  $O_2$  starts at a near-anoxic concentration of  $1 \mu\text{mol-O}_2 \text{ L}^{-1}$  it is possible that  $N_2O$  could be consumed strongly enough to eliminate nearly all of the available  $N_2O$ , but *only if*  $N_2O$  consumption by denitrification is the only process acting on the  $N_2O$  (Figure 68, top). In other words, if a parcel of water at  $1 \mu\text{mol-O}_2 \text{ L}^{-1}$  remained at or near that concentration (only increasing by 0.05% per day) and there was no further  $N_2O$  production occurring, it could theoretically be possible that the  $N_2O$  could be consumed in a few years.

Regardless of differences between the proportion of  $N_2O$  concentration consumed, the residence times for  $N_2O$  are usually high and indicate that  $N_2O$  production by denitrification greatly exceeds  $N_2O$  consumption by denitrification. As mentioned previously,  $N_2O$  production must exceed  $N_2O$  consumption due to the nature of  $N_2O$  as an intermediate between these reaction steps. The results from measuring residence times are important in that they detail how  $N_2O$  production by denitrification *greatly exceeds*  $N_2O$  consumption by denitrification. However, as the  $O_2$  data products used in this model overestimate suboxic concentrations in ODZs (even when applying the Bianchi correction to World Ocean Atlas 2018 data), the model may not account for all of the anoxic and near-anoxic water where  $O_2 < 0.3 \mu\text{mol-O}_2 \text{ L}^{-1}$  in the cores of real-world ODZs. Because of this, there is a chance that global  $N_2O$  consumption is higher than estimated in this research – in such a case, smaller residence times could imply that  $N_2O$  consumption may be more comparable in magnitude to  $N_2O$  production by denitrification within ODZ cores.

The high residence times of  $N_2O$  with increasing  $O_2$  in Figure 68 suggest that once  $N_2O$  is exported from ODZ regions – in particular, the ODZ cores where  $N_2O$  consumption can take place – the  $N_2O$  will stay in circulation for a very long time until it is either released to the atmosphere or encounters another region of water with near-anoxic concentrations. It is possible that there are  $N_2O$  sinks not investigated in this model (e.g., Rees et al. 2021) that are large enough to create regions with an  $N_2O$  deficit or to remove the  $N_2O$  before it is outgassed. As with other reaction pathways that are not included in this model (anammox, DNRA, bacterial vs. archaeal nitrification), further research is needed to understand and quantify the effects of these reactions and their biological relevance in the global ocean.

#### 4.2.3 Relationship between Denitrification Production and Denitrification Consumption

The relationship between denitrification production rates and denitrification consumption rates has also been evaluated by their global rate estimates across a series of sensitivity tests. These rates are related as consumption rates depend on  $N_2O$  as a substrate and the majority of  $N_2O$  is produced by denitrification, especially in ODZs where both processes occur. High denitrification production rates can therefore produce high denitrification consumption rates, and past literature has often debated whether these processes are near-equal in magnitude (Babbin et al. 2015, Kelly et al. 2021, Sun et al. 2021).

To observe this relationship, global  $N_2O$  production and consumption rates by denitrification were compared using a ratio of the two for a series of sensitivity experiments (Figure 69). These experiments include varying the spatial distribution of detritus flux, the exponent  $c$  in  $\Omega$ , the  $NO_3^-$  half-saturation constant for denitrification ( $K_{NO_3,rem}$ ), and the parameter that controls the  $O_2$  concentration dependence of  $N_2O$  consumption ( $K_{O_2,cons}$ ).

**Figure 69:** Ratio of denitrification production rate / denitrification consumption rate for multiple sensitivity analyses. These sensitivity analyses can be found in Figure 32 (organic matter spatial variability), Figure 51 (exponent  $c$  in  $\Omega$ ), Figure 43 (half-saturation constant for suboxic remineralization,  $fNO_{3,rem}$ ), and Figure 53 ( $O_2$  concentration for  $N_2O$  consumption,  $K_{O_2,cons}$ ).

The ratio of global denitrification production rates to global denitrification consumption rates has a consistent value around 2.25. This is more apparent for parameters that affect both reactions (such as the spatial distribution of detritus data products, or  $K_{NO_3,rem}$ ) rather than parameters that cause changes in just one reaction (such as  $K_{O_2,cons}$ ). Varying the exponent  $c$  in  $\Omega$  is an interesting case, as it would be expected that varying  $c$  would affect both denitrification production and consumption – the shape of  $\Omega$  determines how much suboxic remineralization takes place in relation to  $O_2$ , which directly affects denitrification production and so indirectly affects denitrification consumption. The variability of the ratio of production rates to consumption rates by denitrification here is likely a result of how the range of  $c$  values tested shifts  $N_2O$  production towards the upper or lower region of the  $0\text{--}6\ \mu\text{mol-O}_2\ \text{L}^{-1}\ \text{O}_2$  range. More importantly, the ratio never approaches 1 – i.e., denitrification production always exceeds denitrification consumption by a large margin.

The relevance of the ratio of  $N_2O$  production by denitrification to  $N_2O$  consumption by denitrification relates to how denitrification and net  $N_2O$  production influence the nitrogen budget.  $N_2O$  is produced through incomplete denitrification while consumption of  $N_2O$  to  $N_2$  occurs through complete denitrification, and both  $N_2O$  and  $N_2$  production result in a loss of fixed nitrogen (fixed-N) from the ocean. As mentioned in Section 4.1, some past models do not explicitly separate denitrification production and consumption of  $N_2O$ , either assuming that  $N_2O$  production by denitrification becomes zero below a set  $O_2$  threshold due to consumption becoming strong enough to be equal to production (Nevison et al. 2003, Bianchi et al. 2012), or assuming that  $N_2O$  production by denitrification decreases below an  $O_2$  threshold without accounting for an individual consumption term (Suntharalingam et al. 2012, Ji et al. 2018). As

stated earlier, the overlap between these processes and their denotation and parameterization in models leads to considerable confusion in understanding and measuring these reactions.

The total estimated loss of fixed-N through pelagic denitrification – defined here as reduction of  $\text{NO}_3^-$  to  $\text{N}_2\text{O}$  and/or  $\text{N}_2$  – is higher in past models than in this model, with estimates ranging from approximately 50-80 Tg-N  $\text{y}^{-1}$  (Gruber and Galloway 2008, Bianchi et al. 2012, DeVries et al. 2012, Eugster and Gruber 2012, Peters et al. 2018), as well as some estimates reaching higher than 150 Tg-N  $\text{y}^{-1}$  (Codispoti 2007). In comparison, the estimated loss of fixed-N only through  $\text{N}_2\text{O}$  production is lower in past models than in this model, at 2-12 Tg-N  $\text{y}^{-1}$  (see Table 1). In other words, this model projects lower fixed-N loss for total denitrification than past models, but a higher proportion of fixed-N loss attributed to  $\text{N}_2\text{O}$  production rather than  $\text{N}_2$  production.

When accounting for all of the ocean source and sink terms for the nitrogen budget, there are concerns of a large ‘missing source’ term as nitrogen fixation may not provide enough fixed-N to match estimates of fixed-N loss from denitrification (Codispoti 2007). If global estimates for denitrification are smaller than projected by past models, as in this model, it could help reduce the gap between these sources and sinks of fixed-N. Past models that do not separate incomplete and complete denitrification adequately may not be able to account for this larger  $\text{N}_2\text{O}$  production term and so might be overestimating  $\text{N}_2$  production and fixed-N loss through complete denitrification. This model does account for the partitioning of denitrification production and consumption of  $\text{N}_2\text{O}$ , and while this allows for more investigation into the controls of these two processes it is only the first step in understanding and parameterizing the reactions.

Narrowing down the uncertainties listed in the above sections will also require more accurate  $\text{O}_2$  data products in order to reconcile model results and real-world observations. For example, the base case scenario of this model uses a  $K_{\text{O}_2, \text{cons}}$  of 0.3  $\mu\text{mol-O}_2 \text{ L}^{-1}$ , which leads to low  $\text{N}_2\text{O}$  consumption in relation to  $\text{N}_2\text{O}$  production by denitrification. Such a small  $\text{O}_2$  concentration rarely occurs in gridded  $\text{O}_2$  data and is difficult to accurately measure both *in situ* and in laboratory environments. Determining if this very low  $K_{\text{O}_2, \text{cons}}$  is accurate will have large repercussions for the proportion of  $\text{N}_2\text{O}$  production versus consumption by denitrification, and so affect the size of the sink terms for loss of fixed-N by  $\text{N}_2\text{O}$  production and  $\text{N}_2$  production by denitrification.

Existing uncertainties such as  $K_{\text{O}_2, \text{cons}}$  are still not quantified by this research, which highlights the need for improved models with a focus on  $\text{N}_2\text{O}$  and denitrification as well as emphasizing the necessity of maintaining separate parameterizations for nitrification  $\text{N}_2\text{O}$  production, denitrification  $\text{N}_2\text{O}$  production, and denitrification consumption of  $\text{N}_2\text{O}$ . If denitrification occurs more strongly in the global ocean, as anticipated by this research, then better understanding of control by parameters  $thr_{\text{O}_2}$ ,  $c$ , and  $K_{\text{O}_2, \text{cons}}$  are pivotal to estimating fixed nitrogen loss through both  $\text{N}_2\text{O}$  production and  $\text{N}_2\text{O}$  reduction to  $\text{N}_2$ .

## 5 Conclusion

---

This research investigates possible parameterizations of global net N<sub>2</sub>O production in the ocean and tests model sensitivity to uncertain parameters and environmental conditions. In doing so it has confirmed that O<sub>2</sub> has the greatest impact on N<sub>2</sub>O production, followed by availability of organic matter. While the total amount of organic matter input into the model is the initial control on how much N<sub>2</sub>O can be produced, the location of organic matter supply in relation to suboxic regions capable of high N<sub>2</sub>O production rates by denitrification has a greater impact on global N<sub>2</sub>O production estimates. Therefore, the most important influence on estimates of global N<sub>2</sub>O production and consumption is the O<sub>2</sub> data input into the model, and inaccuracies in commonly used interpolated data sets such as World Ocean Atlas result in underestimation of the degree of suboxia and anoxia in the ocean and so the estimated proportion of N<sub>2</sub>O produced and consumed through the denitrification pathway.

Aside from increased O<sub>2</sub> sampling with greater accuracy and precision (especially in and around oxygen deficient zones), future N<sub>2</sub>O studies need to ensure that suboxic O<sub>2</sub> data are not lost to interpolation or to averaging of monthly O<sub>2</sub> data to an annual mean. Such methods can substantially decrease the global volume of suboxic waters capable of denitrification, and in some cases may remove all or most O<sub>2</sub> concentrations below approximately 4 μmol-O<sub>2</sub> L<sup>-1</sup>. When investigating processes that exclusively occur at suboxic O<sub>2</sub> concentrations, such a loss of data is counterproductive to understanding the nature of these reactions.

Global N<sub>2</sub>O production by denitrification was found to exceed N<sub>2</sub>O consumption by denitrification in all tested scenarios, but the relative proportion of these rates are highly sensitive to changes in parameters such as the threshold for denitrification production of N<sub>2</sub>O (*thr<sub>O2</sub>*) and the parameter that determines N<sub>2</sub>O consumption dependence on O<sub>2</sub> concentration (*K<sub>O2,cons</sub>*). The ratio of N<sub>2</sub>O production to consumption by denitrification remains uncertain. Nitrification production of N<sub>2</sub>O in this model provided a very small amount of the total net N<sub>2</sub>O production and is greatly exceeded by net production by denitrification in every scenario tested. While nitrification N<sub>2</sub>O production rates were sensitive to the parameterization of the N<sub>2</sub>O yield (*γ*), changes in O<sub>2</sub> or organic matter availability had more limited effects on nitrification N<sub>2</sub>O production. Since the proportion of N<sub>2</sub>O produced by nitrification in comparison to that produced by denitrification is minor, the sensitivity of global net N<sub>2</sub>O production to parameters that primarily influence nitrification is also relatively minor.

The model's base case scenario suggests high N<sub>2</sub>O production by denitrification (11.4 Tg-N y<sup>-1</sup>) compared to past models (2-12 Tg-N y<sup>-1</sup>, see Table 1). However, the model's estimates of total fixed-N loss by denitrification (19.2 Tg-N y<sup>-1</sup>, including both N<sub>2</sub>O and N<sub>2</sub> production) are low compared to past estimates of approximately 50-80 Tg-N y<sup>-1</sup> (Gruber and Galloway 2008, Bianchi et al. 2012, DeVries et al. 2012, Eugster and Gruber 2012, Peters et al. 2018).

Low estimates of total denitrification in this model may be attributed to a lack of suboxic O<sub>2</sub> concentrations in O<sub>2</sub> data products, inaccurate spatial distribution of EPC (such that less organic matter is available for denitrification in suboxic regions), and/or uncertainties in parameters and parameterizations. The proportion of N<sub>2</sub>O consumed vs. produced by denitrification could also

be underestimated due to a lack of mixing in the model that would transport  $\text{N}_2\text{O}$  to near-anoxic waters where  $\text{N}_2\text{O}$  consumption takes place. The high ratio of  $\text{N}_2\text{O}$  production to  $\text{N}_2$  production may also be a result of  $\text{O}_2$  data products or uncertainties in parameters such as  $K_{\text{O}_2, \text{cons}}$  that influence  $\text{N}_2\text{O}$  consumption. Any increases in total denitrification that would bring the global total closer to historical estimates, however, would also increase the amount of  $\text{N}_2\text{O}$  produced. Based on other literature estimates, it is likely that total denitrification is underestimated and  $\text{N}_2\text{O}$  production is overestimated in this model. The inaccuracies in the  $\text{O}_2$  data set underestimate the volume of suboxic water, which indicates that denitrification may be higher than modelled in the base case scenario. High model sensitivity to uncertain parameters provides a wide range of estimates for global  $\text{N}_2\text{O}$  and  $\text{N}_2$  production by denitrification; however, it is not yet possible to isolate the specific terms that would lead to a resolution regarding the proportion of fixed-N loss to  $\text{N}_2\text{O}$  vs.  $\text{N}_2$  production.

In summary, this research has found that a) global net  $\text{N}_2\text{O}$  production by denitrification greatly exceeds  $\text{N}_2\text{O}$  produced by nitrification, b) denitrification production greatly exceeds denitrification consumption in suboxic regions and in the global ocean, c) total denitrification in the ocean has probably been underestimated in this model due to underrepresentation of suboxic  $\text{O}_2$  in oxygen deficient zones. To improve upon estimates of ocean production of  $\text{N}_2\text{O}$  and understanding of the nitrogen budget and cycling reactions, there is not only a need for more and better observational data, but also a need for future model investigations to maintain nitrification production, denitrification production, and denitrification consumption of  $\text{N}_2\text{O}$  as separate processes. Isolating uncertain parameters such as  $thr_{\text{O}_2}$ ,  $c$ , and  $K_{\text{O}_2, \text{cons}}$  will not be possible without research into the interactions among these individual mechanisms.
